EXISTENCE AND EFFECT OF HIGH BLOOD PRESSURE HELD FOR JURY UNDER CONFLICTING EVIDENCE.

In an action on an insurance policy, defended on the ground of failure to disclose former illnesses, there was medical evidence that the insured's blood pressure in February, 1921, was 250, and was subsequently reduced to 200 and then to 160 and in October, 1921, preparatory to issuing the policy, it was found to be 135, or about normal, and that he had no symptoms of nephritis or arteriosclerosis. It was held, Missouri State Life Ins. Co. v. Witt, Arkansas Supreme Court, 256 S. W. 46, that, the evidence conflicting as to whether the insured had high blood pressure before and at the time the examination was made and the policy issued, and, if his blood pressure had been high, whether it had affected his health or longevity, these things became matters of dispute for the jury.

"When Winter Comes"

—a great many patients—especially the weak and debilitated—need to be fortified against the depressing effects of cold weather, and for this purpose probably no remedy is more widely employed by physicians of experience than

Gray's Glycerine Tonic Comp.

If its use is started early, as soon as the chilly days of Fall begin, this tonic reconstructive will, in the great majority of cases, promptly raise the functional activity of vital organs, and as a logical sequence, produce a marked gain in the defensive powers of the body against germ attack.

Gray's Glycerine Tonic Comp. will thus enable the practitioner to carry many a patient through the Winter with gratifying freedom from the colds, coughs and catarrhal affections in general, that make this period so trying and dangerous to those susceptible to the acute infections.

Valentine's Meat-Juice

Whenever the **Stomach** from any cause **Rejects Food** or **Medicine, Valentine's Meat-Juice** demonstrates its **Ease** of **Assimilation** and **Power** to **Restore** and **Strengthen.** In the **Depressing Prostration** following **Influenza,** and in the **General Debility** of **Phthisis, Valentine's Meat-Juice** is recommended by many practitioners throughout the world as invaluable in their treatment.

Influenza *and* Phthisis.

Dr. Boulland, *Paris, France:* "In an attack of La Grippe accompanied by complete lassitude, I used VALENTINE'S MEAT-JUICE. With this preparation I established an excellent appetite and restored my strength very rapidly."

E. H. Walker, *Resident Medical Officer Boro Isolation Hospital and Boro Tuberculosis Sanatorium, Derby, England:* "I have pleasure in stating that I have found VALENTINE'S MEAT-JUICE valuable in the treatment of soldiers discharged from the Army suffering from Pulmonary Tuberculosis."

Physicians are invited to send for brochures containing clinical reports.

For sale by American and European Chemists and Druggists.

VALENTINE'S
PREPARATION
NUTRIO PERMIT
MEAT JUICE.
The result of an original Process of Preparing Meat, and extracting its Juice by which the elements of nutrition are obtained in a state, ready for immediate absorption.
DIRECTIONS-Dissolve one teaspoonful of the Preparation in two or three tablespoonfuls of cold or warm water. The use of boiling water changes the character of the preparation.

MISCELLANY

The Sachs-Georgi Reaction and Its Significance in the Diagnosis of Latent Syphilis Based on Obstetrical Experiences.—Bela v. Váró (*Wiener klinische Wochenschrift,* May 10, 1923) states that the applicability of the Sachs-Georgi reaction cannot be determined by the percentage of the cases in which the results coincide with those of the Wassermann reaction, inasmuch as the Sachs-Georgi test was positive and the Wassermann reaction was negative in nine cases of latent syphilis without clinical symptoms, in which the suspicion of syphilis was aroused merely by the habitual abortions and the syphilitic premature births. If the syphilitic newborn infants had not been seen these nine cases would have been considered as nonspecific Sachs-Georgi reactions. With the aid of provocative methods the Wassermann reaction was positive half and half in four of these cases. Consequently the Sachs-Georgi reaction is indispensable in the diagnosis of truly latent syphilis (without clinical symptoms). Inasmuch as there are cases of syphilis in which the Wassermann reaction is positive and the Sachs-Georgi test is negative, these two tests do not replace each other but they are complementary to each other. Ever since not only the Wassermann reaction but also the Sachs-Georgi reaction is used in the examination of the blood of mothers of syphilitic newborn infants, not one woman was found which could be classified in accordance with Colles's law; these were all found to be syphilitic. Consequently there are no syphilitic newborn infants without a syphilitic mother. According to the findings with the Sachs-Georgi reaction this law is untenable.

Origin and Diagnostic Value of the Cutaneous Striæ During Pregnancy.—P. Sfameni (*Zentralblatt für Gynäkologie,* May 5, 1923) states that the formation of striæ on the abdomen depends upon the following factors: 1, the increase in the volume of the abdominal contents; 2, the deposition of fat in the subcutaneous cellular tissue; and 3, the simultaneous coincidence of both of these factors within a short time. For this reason pregnancy almost always produces abdominal striæ, whereas ascites and tumors almost never produce abdominal striæ. The striæ on the breasts are due to the deposition of fat and the hypertrophy of the milk gland. Abdominal and mammary striæ are associated almost exclusively with pregnancy and therefore have a considerable significance in the diagnosis of pregnancy. The striæ on the thighs are produced only by a rapid deposition of fat. Their significance in the diagnosis of pregnancy is almost nil. The striæ on the abdomen, the breasts, and the thighs show variations in direction, arrangement and in structure. This is due to the varying tension to which the skin in the different regions, and especially the anatomical conditions, is subjected.

Syphilis and Pregnancy.—H. Thaler (*Wiener klinische Wochenschrift,* April 19, 1923) calls attention to the fact that in syphilis an unusual enlargement and increased weight of the placenta is frequently demonstrable; it is also characterized by a considerably increased firmness and a pale red color. The histological changes in the placenta include a marked widening of the chorionic villi from proliferation and edema of their connective tissue and their bloodvessels show more or less complete localized obliterations from endarteritis and endophlebitis. The epithelium frequently shows defects and in some places proliferation. The villi are frequently adherent, forming larger complexes, or they may be separated by narrow intervillous spaces carrying but little blood. These changes constitute an important index for the demonstration of fetal syphilis, but they may also be found in syphilitic women in connection with nephritis or after fetal death without the occurrence of syphilis. Spirochetes may be more or less numerous in syphilitic placentas and also in placentas almost normal; they are also found within the intervillous spaces and in apparently normal villous epithelium just at the time of their passage through them. The healthy placenta does not act as a filter to spirochetes. The umbilical cord of syphilitic fetuses often show inflammatory changes in the vascular walls in the form of small celled infiltrations, especially near the fetal end, affecting mainly the media and adventitia. The Wassermann reaction is not a reliable index of syphilitic infection as it shows eight to ten per cent. of nonspecific reaction during pregnancy and negative reactions in actually infected infants.

In the matter of prophylaxis, at least five years should have elapsed between the infection and marriage of a syphilitic individual, of which period the last three should be free from syphilitic manifestations of disease. The Wassermann reaction should be negative on repeated examination for at least one year. Even though these conditions are fulfilled, an existing possibility of the transmission of syphilis cannot be definitely excluded. The treatment of syphilis during pregnancy should be the usual course of treatment. Arsphenamine is well borne and increases the chances of life in the infant. In syphilis a fever frequently develops during the puerperium. The course of syphilis is affected by pregnancy in the sense that it is often more severe and the tendency to recurrences is increased.

Effects of Lysozyme.—Onari Nakamura (*Wiener klinische Wochenschrift,* May 3, 1923) confirms the finding of a solvent action of tears and of chicken egg albumen upon saprophytic bacteria, especially sarcinæ in a dilution of 1:100,000 and their comparative resistance to heat. They also act on dead microorganisms and do not lose any of their activity on repeated use. One eight thousandth normal acid increases their effect. Acids which are stronger than 1:2000 normal inhibit it, but an overneutralization by alkali results in a rapid dissolution of the organisms, even though the amount of tears originally added would not have been sufficient to obtain it. Some sarcinæ are resistant to tears.

Treatment of Beginning Incarceration of the Retroflected Gravid Uterus.—F. Unterberger (*Zentralblatt für Gynäkologie,* May 5, 1923) recommends the elevation of the retroflected gravid, incarcerated uterus by strapping the patient for ten to fifteen minutes in a position of marked elevation of the pelvis, which should be repeated one or more times. The success of this maneuvre depends apparently upon the suction power of the uterus as a result of the negative pressure. Every maneuvre of straightening the uterus by way of the vagina should be omitted.

Constipation in Young Girls and Women—

especially those who spend much time indoors engaged in sedentary pursuits—is almost invariably attended by a retention of waste and toxic substances. Sooner or later these make their way from the bowel into the general system and give rise to a host of auto-toxic ills.

Correction of this condition is imperative, and the safest, simplest and most effective remedy for the purpose is

INTEROL

Directions:

To relieve the constipation of young girls and women, give two to four teaspoonfuls of INTEROL morning and night, increasing or decreasing the quantity as conditions require. As the bowels yield to the action of INTEROL, gradually cut down the dose to the least amount that—taken at bedtime — will assure a daily evacuation.

a pure mineral oil of the proper density and viscosity to assure satisfactory lubrication of the intestinal canal, and thus relieve and correct bowel inactivity without the usual disagreeable effects of cathartics as commonly employed.

Besides lubricating the canal, INTEROL renders the feces soft and plastic, thereby promoting their easy passage and evacuation with gratifying freedom from discomfort and distress.

It would indeed be difficult to suggest any more serviceable and agreeable medium for the correction of constipation, with its attending autotoxemic conditions, than INTEROL.

Sample and Interol brochure on request.

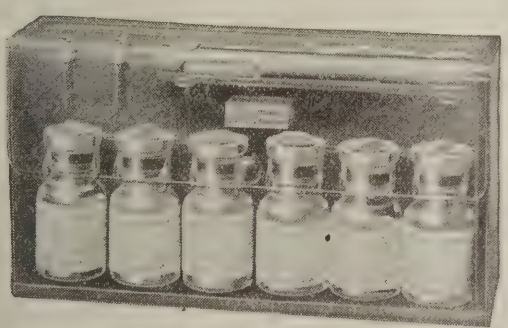
Does Heat Injure Vaccines?

THE recommendation of most Biologic Manufacturers is that their products be kept on ice. If room temperatures are deleterious to these vaccines what happens to them when they are heat sterilized? Sherman's Vaccines are sterilized without heat.



On presentation of this advertisement to your druggist you will be entitled to this genuine leather case arranged to hold six 12½ c. c. vials, and an all glass self-sterilizing syringe with two gold tempered needles gratis with your order for any six vials of Sherman's Vaccines. If your druggist can not supply you we will be pleased to furnish your requirements until local distribution satisfactory to you can be arranged.

Effect of Milk Acquired in an Aseptic Manner and Injected Parenterally in Various Internal Diseases.—F. Högler and F. Seidel (*Wiener klinische Wochenschrift,* May 3, 1923) assert that the unfavorable effects of parenteral injection of milk are due to the presence of microorganisms and toxins in the milk. If milk is acquired in an aseptic manner and sterilized, the intramuscular injections of five to ten c.c. of milk thus acquired are rarely followed by fever or subjective disturbances. The authors saw favorable results in such conditions as arthritis, bursitis, tendovaginitis and in bronchitis. They also observed a distinct diuretic action about eight to twelve hours after the injections. This may have some bearing on the effect of the treatment of inflammatory edemas. Inasmuch as the same results are obtained as with ordinary sterilized milk, the curative effects are not due to the fever but to the colloidal elements of the injected milk. The fever is apparently due to the toxic admixtures.

Experimental Tar Carcinomas in Mice.—B. Lipschütz (*Wiener klinische Wochenschrift,* July 6, 1922) found pigmented tumors in gray mice (but not in white mice) which were located in the corium and consisted of true melanoblasts. He also describes certain changes in the sebaceous glands, following the local application of tar. Both of these pathological lesions are not the results of the local action of the tar as they are also found in regions which are far removed from the areas not coated with the tar. It was also impossible to produce pigmented tumors by implantation in animals that were not painted with tar.

Hydrogen Ion Concentration of the Blood in Carcinoma.—William H. Chambers (*Journal of Biological Chemistry,* February, 1923) determined the hydrogen ion concentration of the dialysate from the venous blood in forty-five cases of carcinoma. At 20° C. it averaged 7.45, which was slightly more alkaline than that of normal subjects, 7.31. In general, the degree of alkalinity corresponded to the size and extent of the tumor growth, small tumors without metastases showing little or no increase above the normal. The second part of this study was done by Chambers and R. E. Kleinschmidt. The CO_2 content and the CO_2 tension were determined in the venous blood of normal individuals, and from carcinoma cases and various other pathological conditions. The venous CO_2 tensions were read from the CO_2 absorption curves which were plotted at the venous oxygen tension, or from those plotted from fully oxygenated blood with a correction for venous oxygen unsaturation. The hydrogen ion concentration of the blood was calculated from the CO_2 bicarbonate ratio. The average reaction of twelve determinations on normal bloods was pH 7.29, of eight determinations on diseases other than carcinoma it was 7.33, and of twenty-three determinations on carcinoma patients it was pH 7.34. It is concluded from these results that there is no evidence of an actual decrease in H ion concentration of the blood in carcinoma which can be related primarily to the cancer. In normal bloods the colorimetric determination of the pH of the dialysate at 20° C. agreed within experimental error with the pH of the venous blood at 38° C., calculated from the CO_2-bicarbonate ratio.

Mechanism of Phlorrhizin Diabetes.—Thomas P. Nash, Jr., and Stanley R. Benedict (*Journal of Biological Chemistry,* April, 1923) produced a hyperglycemia maintained for six hours or longer in phlorrhinized dogs, and a quantitative excretion of the dextrose fed was noted. They believe that phlorrhizin does produce an intrinsic impairment of utilization of sugar by the tissues, not only of the kidney, but all other metabolizing tissues also. A mixture of dextrose and urea was ingested by the phlorrhizinized dogs, the sugar being more rapidly excreted in the urine than the urea, which is a result comparable to that observed by feeding meat and proteins to dogs.

Experimental Kidney Lesions in Rats.—In producing kidney lesions in rats by diets defective only in that they contained excessive amounts of proteins, L. M. Polvogt, E. V. McCollum and Nina Simmonds (*Bulletin of the Johns Hopkins Hospital,* May, 1923) fed young rats on diets, the protein content of which varied from 31 to 41.3 per cent. Aside from this high protein content all the diets were well constituted. When the animals were between 250 and 400 days old they were killed and autopsied. All the rats on the high protein diet had kidney lesions of considerable severity. The kidneys were large and apparently hemorrhagic. Microscopical examination showed marked congestion. The outstanding feature was the formation of large numbers of hyaline casts and the intense congestion. Apparently no cause other than the excretion of excessive amounts of the end products of protein metabolism was responsible for the renal damage described.

Treatment of Auricular Fibrillation by Quinidine Sulphate.—J. G. Emanuel (*Lancet,* May 26, 1923) follows the original doses recommended by Frey, viz., 0.4 gram (approximately six grains), given in capsules by mouth. One dose is given the first day, two the second, three the third, and so on till a maximum of ten doses may be reached. This large number, however, is rarely necessary, the majority of the patients being restored on the second, third, or fourth day. The dose is repeated every two hours and it is convenient to give the initial dose at 5 a. m., so that on the fourth day of administration, for example, the patient has a capsule at five, seven, nine, and eleven o'clock in the morning. The pulse is reported hourly, and if necessary the nurse is instructed to estimate the ventricular rate from the apex beat. She records not only the rate, but also the rhythm, adding the word regular or irregular to the pulse chart. The quinidine is discontinued as soon as a regular rhythm is noted, and the patient, who has been kept in bed during the administration of the drug, is allowed up on the following day. Electrocardiograms are taken as controls as often as may be found necessary. No rhythm is accepted as sinus rhythm without confirmation by the electrocardiograph. It is important that the intervals between successive doses of quinidine should be short, as it is rapidly eliminated. It is undesirable to give digitalis and quinidine at the same time. Rest in bed and digitalis must first bring about such an improvement in the degree of heart failure that no further benefit can be obtained from the digitalis. Digitalis is a specific remedy and quinidine an invaluable coadjutor in the treatment of cardiac failure with auricular fibrillation.

"When Winter Comes"

—a great many patients—especially the weak and debilitated—need to be fortified against the depressing effects of cold weather, and for this purpose probably no remedy is more widely employed by physicians of experience than

Gray's Glycerine Tonic Comp.

If its use is started early, as soon as the chilly days of Fall begin, this tonic reconstructive will, in the great majority of cases, promptly raise the functional activity of vital organs, and as a logical sequence, produce a marked gain in the defensive powers of the body against germ attack.

Gray's Glycerine Tonic Comp. will thus enable the practitioner to carry many a patient through the Winter with gratifying freedom from the colds, coughs and catarrhal affections in general, that make this period so trying and dangerous to those susceptible to the acute infections.

VALENTINE'S PREPARATION
NUTRIO PERMIE
MEAT JUICE.
The result of an original Process of Preparing Meat, and extracting its Juice by which the elements of nutrition are obtained in a state, ready for immediate absorption.
DIRECTIONS-Dissolve one teaspoonful of the Preparation in two or three tablespoonfuls of cold or warm water. The use of boiling water changes the character of the preparation.

MISCELLANY.

Acute Industrial Mercurial Poisoning.—As a result of his experiences Max Winkler (*Schweizerische medizinische Wochenschrift,* August 19, 1923) comes to the conclusion that wherever industrial plants, in which mercury is used, are built, care should be taken to supply, in the first place, plenty of fresh air and good ventilation. The mercury should be kept in closed spaces, as it evaporates even at the ordinary temperature. The floors should be covered with a thick layer of lead, so that any spilled mercury can roll off and be collected below. The entire distillation apparatus should be airtight. Workmen should change their clothes on leaving the workshop; they should wash their hands and face and they should practise careful oral hygiene, which should consist of washing the mouth with alum (which is the cheapest remedy) and brushing the teeth and the gums. Carious teeth should be removed or their cavities should be filled. Smoking should be restricted to a great extent and the chewing of tobacco should be avoided.

Antiseptic Action of Some Benzyl Compounds.—David I. Macht and Justina H. Hill (*Bulletin of the Johns Hopkins Hospital,* May, 1923) made a bacteriological study of benzyl alcohol, benzaldehyde, benzyl benzoate, benzyl acetate and a number of natural pharmacological compounds containing benzyl bodies, such as benzoin, balsam of peru, oil of cajuput, and a number of others. Cultures of Staphylococcus pyogenes aureus were exposed to the action of the various drugs at different time intervals, as one minute, one, three, and five hour exposure. Dilutions of the drugs were made with sterile cottonseed oil. Benzyl alcohol, even when diluted with oil, exhibits definite antiseptic properties. Every one of the compounds examined showed a definite germicidal and antiseptic effect. This bactericidal property of the benzyl compounds throws light on the beneficial results following the use of tincture of benzoin in the form of inhalations in the treatment of sore throat, and in various lotions and skin preparations. The antiseptic power of benzaldehyde and benzyl alcohol was found to be much greater than that of other drugs used by laryngologists, such as guaiacol and menthol.

Lymphangitic Abscess of the Neck.—P. Clairmont (*Schweizerische medizinische Wochenschrift,* May 3, 1923) describes the occurrence of a typical abscess which occurs in the lower anterior portion of the neck, in the paries anterior triangle, between the thyroid gland and the sternocleidomastoid muscle, beneath the middle fascia of the neck (cervical aponeurosis) and therefore dorsal to the small muscles of the neck, which should be considered as a lymphangitic abscess. It may develop from various causes. Clinically it resembles suppurative thyroiditis. With incision the prognosis is favorable. The anatomical conditions responsible for its development are the course of the lymph tract with the bloodvessels, the arrangement of the lymph nodes, the crossing of the omohyoid muscle of the common jugular vein and the associated fascial relationships. It is still undetermined whether an enlargement of the thyroid lobes on the diseased side plays any important part in the development of the abscess.

Corpus Luteum Cysts and Persistent Corpus Luteum.—L. Fraenkel (*Zentralblatt für Gynäkologie,* August 5, 1922) shows the great clinical significance of corpus luteum cysts as the cause of extensive perimetritides and functional abnormalities, such as amenorrhea, hemorrhages and sterility. This disease picture is the analogue of the persistent corpus luteum of animals. The cysts are usually flaccid and give a feeling of diffuseness. If amenorrhea or an apparently premature menstruation has preceded and if blood is aspirated from the cyst, it may be confused with extrauterine pregnancy. Small, movable cysts, occurring in tubal pregnancy, arise from the corpus luteum verum and retrogress with the pregnancy, just as do the multilocular cysts in hydatidiform mole.

Almost every form of inflammation about the genitals leads to corpus luteum cyst formation; they are often associated with myomata. Sensitive, enlarged adenxa, which are not due to plainly palpable tubal swellings or to microcystic degeneration of the ovaries, are almost always corpus luteum cysts. Tubal swellings are usually complicated by these cysts and tuboovarian abscess is usually due to secondary suppuration of the cystically degenerated corpus luteum. Isolated ovarian abscesses are always localized in the corpus luteum.

The etiology is frequently uncertain; gonorrhea is often no etiological factor. The corpus luteum hormone, probably, produces irritation in the peritoneum surrounding the cyst and the inflammatory character of the disease. Bacteria are usually absent in the cysts; there is no fever, but there are severe pains, radiating into the legs, back, hips and sciatic nerve. The adhesions are frequently dense and firmly attached. The chief symptoms are absent or premature menstruation and severe hemorrhages. A true corpus luteum persistens, as seen in cattle, rarely occurs in women, but the cysts, originating from the last corpus luteum, are unusually common. Inasmuch as a subsequent development of the corpus luteum is always absent, this condition is probably the equivalent of the corpus luteum persistens. These cases are also associated with another important symptom—primary or acquired sterility and, more rarely, habitual abortion. Sterility may occur also with a patent corresponding tube or noninvolvement of the adnexa of the other side. Conception occurs rarely because the corpus luteum cyst prevents subsequent ovulation or the normal embedding of the ovum.

The treatment is always laparotomy; curettage and the resorption treatments are ineffective. The proper procedure is enucleation of the cyst and resection or extirpation of the ovary. The digital nonoperative rupture is condemned. The laparotomy discloses the cause of the sterility—corpus luteum cyst, agglutination of the tubal fimbriæ and the ovary buried in sacs of adhesions. The author practises curettage of the tubal mucosa with a small curette; also a transverse incision in the fundus with opening of the uterine cavity, salpingectomy, tunnelling of the cornua uteri, and implantation of the healthy tube from another woman, operated on simultaneously for prolapse; the excised tube is freed from the peritoneum in the position nearest the median line and implanted from the uterine cavity outward.

In recommending an infant food —consider its nutritive value first

Cleanliness, digestibility, and palatability are also of importance, but without nutritive value any food would be useless as a body builder.

FOR the infant, breast milk furnishes all of the requirements mentioned. There is no need to seek further for a better food because no one has as yet been able to prepare a formula which can be considered anything other than a second choice.

As a breast milk substitute there is no better food for the infant than Eagle Brand Milk. For more than four years the largest child-feeding clinic in the history of the world has been maintained in the Near East, and Eagle Brand Milk has met every requirement for a complete milk food for the infants and older children throughout this period.

Reprints of clinical experiments with sweetened condensed milk will be sent upon request.

HACKENSACK, - - - - - - NEW JERSEY, U. S. A.

Actinomycosis.—W. W. Mattson (*Surgery, Gynecology and Obstetrics,* April, 1922) concludes as follows:

1. There is but one true species of microorganism capable of producing actinomycosis in man and lower animals and this is the one isolated by Wolff and Israel and later more fully described by Wright. 2. There is no convincing clinical evidence supporting the theory that this organism is a normal inhabitant of the oral cavity and gastrointestinal tract of man. 3. There is much clinical and biological evidence that this microorganism has its source outside of the human body and is capable of a dual existence: first as a saprophyte in old sod soil from which it gains access to grains and grasses and through this medium or intermediary host so to speak, it becomes capable of infecting man and lower animals. 4. In order that infection may take place two things are necessary: first, an abrasion of the tissues: second, the fungus must in some way be brought directly in contact with this abrasion. 5. Animal to man infection is far more common than we have been led to believe it was by earlier investigators. 6. Human actinomycosis is not a rare disease, but a disease which is often overlooked or incorrectly diagnosed. 7. Every inflammatory swelling of chronic or subacute nature with persistent and recurring sinus formation should be carefully investigated for this disease. 8. A negative smear, on first examination, does not rule out infection, as the fungus, in the presence of mixed infection, is often very difficult to find. 9. The disease should always be kept in mind in every case of atypical pulmonary tuberculosis and should be looked for in cases with chronic purulent bronchitis or bronchiectasis. 10. Early treatment of superficial lesions are highly successful. Internal infections are extremely fatal and hopeless.

Dried Milk.—Timothy Leary (*Boston Medical and Surgical Journal,* May 4, 1922) quotes from the British report:

"The physical and chemical changes produced by the processes used in the preparation of dried milk so alter its character that it is better borne by the infant's stomach than ordinary cow's milk, whether raw, boiled or sterilized. The dried milk is easily and completely assimilated. It is palatable. Millard says the babies like it and do not relish any change. The effect on nutrition is very marked. Where weight charts have been kept regularly, they show a steady advance, and the child's flesh is firm and solid, not flabby, and the general tone and condition good."

He goes on to say that little argument is needed to demonstrate the advantages which should arise from the elimination of the substance, i. e., water, which gives to milk its perishable quality.

Hygienically, the milk borne epidemic, either originating from the milk as drawn *a,* or from contamination during handling *b,* should be done away with. The drying process should eliminate the organisms, such as streptococci, producing the first form of epidemic. The second form, as illustrated by typhoid, is dependent upon the multiplication of the original contaminating dose of bacilli in the fluid milk. The drying of the product makes improbable the successful multiplication of the bacteria or their wide distribution throughout the product.

Economically, all of the emergency procedures which are necessary in the handling of liquid milk would be done away with, refrigeration, special cars, breakable special containers, and most of all special delivery.

A hidden cost of milk, which does not appear in the lists of costs submitted, arises from the public inspection of the sources of supply, and the further laboratory investigation of the quality and cleanliness of milk as delivered. This latter cost, necessitated largely by the tendency of milk to deteriorate in handling, could be in part done away with if the use of powdered milk were universal. The only inspection necessary would be the inspection at the source, and this could be made more rigid for less money than is now expended for the present double inspection, i. e., at the source and at the point of delivery.

The development of the present day apparatus for milk drying along indicated lines should make it possible for milk producers, individually, or in groups, to powder their own milk at the source, thus becoming independent, to a degree, of seasonal demands, and this should cheapen the price of milk to the consumer.

Aesthetically, the rumble and reverberation of the milk wagon in its nightly disturbance of the peace would be abolished, to the joy of the insomniac, and the better rest of the deposed milk driver and his family.

An important drawback to the universal use of milk powder is its price. It costs today, at retail, apart from the trouble of its preparation, more than liquid milk. When one considers the cost of the emergency features in the handling of liquid milk, which do not enter into the cost of powdered milk, one is puzzled to account for its retail price, seventy to seventy-nine cents a pound, and further puzzled when one learns that the same milk powder sells in barrel lots at thirty-three to thirty-five cents a pound. Milk powder is slightly hygroscopic, and for retail purposes has to be put up in tin, but the cost of a tin container does not markedly add to the cost of most food products. It is possible that introductory advertising is an important factor in elevating the price. If so, wider use and competition should serve as correctives.

The Facies of Heredosyphilis, With Comment on Its Possible Embryogenesis and Its Confusion With Oxycephaly and Congenital Ectodermal Defect.—John H. Stokes (*The Medical Clinics of North America,* July, 1923) believes that the facies of heredosyphilis is most conveniently regarded, in the absence of definite knowledge of the underlying developmental mechanism, as the result of a twist or embryonal dysplasia, the result of the syphilitic intoxication perhaps, rather than of the spirochetal invasion of the affected tissues as such. It should, therefore, be distinguished from the deformities induced by gummatous osteitis of the nasal and cranial bones. The value of the facies in affording a clue to a heredosyphilitic factor in a variety of conditions in childhood and adult life should be better appreciated, but due precaution should be used in the interpretation of this element in a diagnosis. The possibility of confusion with the clinical picture of mild grades of oxycephaly and with the facies of congenital ectodermal defect should be borne in mind.

"When Winter Comes"

—a great many patients—especially the weak and debilitated—need to be fortified against the depressing effects of cold weather, and for this purpose probably no remedy is more widely employed by physicians of experience than

Gray's Glycerine Tonic Comp.

If its use is started early, as soon as the chilly days of Fall begin, this tonic reconstructive will, in the great majority of cases, promptly raise the functional activity of vital organs, and as a logical sequence, produce a marked gain in the defensive powers of the body against germ attack.

Gray's Glycerine Tonic Comp. will thus enable the practitioner to carry many a patient through the Winter with gratifying freedom from the colds, coughs and catarrhal affections in general, that make this period so trying and dangerous to those susceptible to the acute infections.

VALENTINE'S
PREPARATION
NUTRIO PERFICIE
MEAT JUICE.
The result of an original Process of Preparing Meat, and extracting its Juice by which the elements of nutrition are obtained in a state, ready for immediate absorption.
DIRECTIONS-Dissolve one teaspoonful of the Preparation in two or three tablespoonfuls of cold or warm water. The use of boiling water changes the character of the preparation.

Miscellany.

Functional Elongation of the Thigh.—O. Frisch (*Wiener klinische Wochenschrift,* July 26, 1923) states that in order to relieve a shortening of the femur of a severe grade in an existing ankylosis of the hip, the oblique osteotomy with a subsequent extension is not sufficient and an attempt must be made to make the healing of the osteotomy wound take place in a degree of abduction commensurate with the shortening, whereupon the shortening is functionally corrected by the obliquity of the pelvis. The angle of abduction necessary to obtain this correction may be calculated from the existing shortening, the width of the pelvis and from the length of the thigh. The variations in the calculation dependent upon the physiological variations of this measurement are so slight (except in special conditions) that the same scheme may be used for all adults. On the basis of this finding, it may be said that one cannot go wrong in selecting about double the amount of abduction as the shortening amounts to in centimetres. The scoliosis of the lumbar portion of the spine necessary therefore as a result of physiological limits allows at the most an obliquity of the pelvis which corresponds to an abduction of the leg of 35°, whereby a shortening of fifteen cm. may be corrected. This functional elongation of the leg as a result of the obliquity of the pelvis may be combined as a secondary procedure with the extension after oblique osteotomy.

Blood Grouping and Its Clinical Applications: With a Simple Method of Group Determination.—S. C. Dyke (*Lancet,* March 25, 1922) states that it has been proved that two agglutinable substances (A and B) reside in the corpuscles and two corresponding agglutinins reside in the sera (a and b) and that the active agglutinin in a given red cell is never normally present in the serum associated with that cell, and conversely, that the agglutinin opposite in sign to that of the red cell is always present in the serum of that blood. There are four groups, called groups i, ii, iii and iv, of which group iv is the socalled universal donor, and members of this group can receive blood only from a member of this group; group i is the socalled universal recipient; groups ii and iii can act as donors only within their own group or group i and can receive blood only from members of their own group or group iv. This grouping simplifies the selection of donors. In practice a number of group iv donors should always be available.

The determination of the blood group of any individual may be done in a few minutes, requiring only the possession of known group ii and group iii sera and the testing of the red cells (agglutination). Corpuscles agglutinated by both group ii and group iii sera belong to group i; those agglutinating group iii sera but not group ii, belong to group ii; those agglutinated by group ii sera but not by group iii sera belong to group iii, and those agglutinated by neither group ii nor group iii sera belong to group iv. The simplest technic is to divide a glass slide into halves by a grease pencil, marking one half ii and the other iii and placing a small drop of blood on each half; a large drop of known group ii serum is dropped on the half marked ii and the blood is mixed; the same procedure is followed with a known group iii serum. The slide is occasionally agitated and read off after fifteen minutes by the naked eye.

The principal clinical application of blood grouping is in the field of blood transfusion; it has been recommended also for the selection of donors in skin grafting and in medicolegal cases: 1, in narrowing down the possibilities of individuals from whom a given sample of blood may have originated and 2, in the determination of paternity.

Further Observations of the Pharmacology of Benzyl Compounds.—Carl Nielsen and John A. Higgins (*Journal of Laboratory and Clinical Medicine,* July, 1922) as a result of their continued studies on benzyl compounds report the following conclusions: Their observations suggest that the relaxing power of benzyl esters on the smooth muscle fibres of the intestine as a rule is dependent upon the benzyl content and upon the rate of hydrolysis of the benzyl compound. In all cases where successful comparative records were obtained, with the exception of those of benzyl salicylate and benzyl acetylsalicylate, the higher the rate of hydrolysis, the greater the efficiency proved to be. Benzyl fumarate was more efficient than benzyl succinate, especially in regard to initial action; the succinate was more efficient than the stearate, the acetate more powerful than the cinnamate, and the latter was of higher efficiency than the benzoate. The high relaxing power of benzyl salicylate and benzyl acetylsalicylate, in spite of their slow rate of benzyl hydrolysis, may be attributed to their intact molecules. These compounds differ from other benzyl esters in that their molecules contain hydroxyl or substituted hydroxyl groups. The benzyl acetylsaliciylate is more efficient as an intestinal relaxant than the salicylate, in fact it is more powerful than any of the benzyl esters investigated. Various benzyl compounds other than benzyl esters, namely benzyl phenolate, benzyl ethyl ether, and monobenzyl barbituric acid, as well as benzaldehyde, were also found to possess smooth muscle relaxing properties.

Effects of Excess of Calcium on the Skeleton.—As a result of his experiments, V. Korenchevsky (*British Medical Journal,* May 12, 1923) draws the following conclusions: 1. Butter bought in the winter may contain a considerable amount of the antirachitic principle. 2. When the amount of calcium in a normal diet containing eight per cent. butter and two per cent. codliver oil was increased two or three times, the calcification of the skeleton was either not increased at all or only slightly. 3. The ingestion of even very large quantities of calcium did not cure the rachitic calcium impoverishment of the skeleton of rats on a diet deficient in the fat soluble factor. 4. When the exhaustion of the fat soluble factor in the body of rats is not complete, an excess of calcium in diets deficient in fat soluble factor may in some cases slightly increase the amount of calcium in the skeleton, though never sufficient to make the calcification normal. 5. On the basis of the data of the chemical and histological examination, the skeletal affections in rats on a diet must be classed in the group of rachitic affections, which develop even with an excess of calcium in the diet.

Sluggish Bowel Action in Childhood

is usually due to errors in feeding. Subjecting these fundamentals to the customary careful correction,

INTEROL

may be administered coincidentally to relieve the immediate condition.

This pure, tasteless and odorless mineral oil—notably free from the greasiness common to such products—has proved of exceptional value as a safe and dependable means of moving the bowels of young children, and this without the griping, straining and after-constipation by which the use of castor oil and other drastic cathartics is so frequently attended.

Dosage in Children

Begin with a half to one teaspoonful, 3 times a day before meals. Increase or decrease dose until one good movement is obtained daily. Then gradually decrease to the point where a small dose at bedtime will maintain this result.

The constantly-growing number of physicians who prefer INTEROL to any other media in the routine management of constipation in early life is its own best endorsement.

Sample and Interol brochure on request.

ACKENSACK, ... NEW JERSEY, U. S. A.

Rubella Without a Rash (Rubella Sine Exanthemate).—According to the observations of G. Flöystrup (*British Journal of Children's Diseases,* January-March, 1923), cervical and occipital adenitis is a very frequent phenomenon in rubella (while the glands in measles are swollen much less frequently and in a much slighter degree). The enlargement, therefore, must be regarded as of much greater diagnostic importance than is supposed by most authors. The adenitis is all the more valuable diagnostically as it appears about a week before the rash, and so permits the diagnosis of rubella, though not with complete certainty, and thereby perhaps hinder the spread of the disease. The possible occurrence of rubella without a rash is mentioned in the literature for the first time.

Causes of Stillbirths and Neonatal Deaths.—Harold Bailey (*Archives of Pediatrics,* April, 1923) found that the fetal mortality of childbirth is due to several causes but prematurity stands foremost with trauma due to dystocia as a close second. As the deaths from prematurity occur in the antenatal, intranatal, and neonatal periods, the present methods of prenatal service can be of very little use. The causes of premature emptying of the uterus should be investigated by the trained biochemist and the internist. Possibly a low grade toxemia causes degeneration of the placenta and is thus the origin of the trouble. Premature infants do not stand operative trauma and in all abnormal deliveries this should be taken into consideration. The postnatal care of those who survive should be placed in the hands of competent obstetricians. In the author's series of cases, syphilis was not a common cause of stillbirth or death during the first month of life. Abortions and miscarriages should be separated in the health reports from those deaths that occur after the period of viability and the weight and length of the fetus should be the determining factor.

Köhler's Disease of the Tarsal Scaphoid.—H. B. Greenwood, (*Lancet,* August 11, 1923) maintains that no real causa causans emerges from a theory of dystrophy or delay in ossification later stimulated to osteogenesis by trauma. Indeed, a history of trauma could probably be obtained in every case by careful and persistent investigation, especially if the period inquired into is allowed to stretch as far back as two years before the detection of the disease, and to include injury of any degree of severity. The author believes that in a child the subject of a latent mild tuberculous infection there is lighted up (possibly by an injury of moderate severity) a smouldering tuberculosis of the scaphoid bone of the foot, the bone which, the keystone of an arch, is most subject to strain, stresses, and blows. The early stage, evidenced by a rarefying osteitis, gives rise to such trifling clinical signs that no complaint is made, no x ray examination carried out and the disease escapes recognition. Should the disease progress and spread to neighboring bones the case is diagnosed as a frank tuberculosis of the tarsal bones. But should resolution occur and a reparative sclerosis take place, either no diagnosis other than sprain or incipient flatfoot is made, or an x ray examination is made, and the condition found is called Köhler's disease. It is natural then that recovery should always occur since the disease is already recovering when detected.

Miscellany.

Clinical Studies on Insulin.—Nelson G. Russell, Byron D. Bowen and George W. Pucher (*Bulletin of Buffalo General Hospital,* April, 1923) report on the treatment of six cases of rather severe diabetes with iletin. The results obtained appear to be in accord with other investigations and suggest the possession of another means of managing these cases in addition to the restriction of diet, especially in the severe cases in which dietary treatment alone is unsatisfactory and often useless. This study does not give convincing information on the proper time of administration with relation to meals or on the number of daily doses resulting in the most economical use of the extract. These points possibly differ in individual cases and require further investigation. The tolerance was quite definitely increased in one case and slightly so in another, but if these patients had received dietary treatment prior to the administration of iletin, an increased tolerance might not have been effected. It may be futile to determine the total glucose-iletin ratio, but in this series of cases the ratio appears to be quite constant—two to three grams of glucose equals one unit of iletin. There were no reactions or untoward results, which is attributed to the following: 1. Iletin appears to be a carefully standardized, biological product. 2. The cases were all severe. 3. Care was taken to keep the blood sugar well above normal. One patient was twice restored to consciousness from deep diabetic coma by the use of iletin. The effects of iletin upon the utilization of glucose is striking.

The Modern Treatment of Congenital Syphilis and Its Results.—J. Bernheim-Karrer (*Schweizerische medizinische Wochenschrift,* July 19, 1923) states that with salvarsan-mercury treatment, the affections of the skin and mucous membranes are healed the quickest of all. With enlargements of the liver and spleen the results are just as rapid. Palpable cubital lymph nodes frequently persist in spite of a negative Wassermann reaction. These may be the result of infections on the fingers. Recurrences of the skin and mucous membranes may appear after the first course of treatment. Neuroretinitis does not always disappear after specific treatment. Renal complications, in contrast to their occurrence in adults, are no contraindication to the salvarsan or mercury treatment. If possible, the salvarsan is injected into a vein of the head, but never into the longitudinal sinus because of the danger of necrosis; if this is impossible, it is injected into the gluteal musculature. The rule now followed, is to begin with 0.015 gram of neosalvarsan. This dose may under certain circumstances be increased to double this amount. No harmful results were seen to follow this dosage. This antisyphilitic treatment is interrupted temporarily only in the occurrence of an acute intercurrent disease, such as grippe or a severe disturbance of nutrition. Calomel is never given in larger doses than 0.001 gram per kilogram of weight and usually no more often than once a week. Calomel produces infiltration and the resulting danger of poisoning from subsequent sudden resorption of mercury much more often than does salvarsan.

Artificial Glycosuria From the Ingestion of Sugar in Pregnancy.—Albert W. Bauer (*Zentralblatt für Gynäkologie,* September 2, 1922) concludes that although the artificial glycosuria following the ingestion of glucose cannot be used as a sign of differential diagnosis between extrauterine pregnancy and tumor of the adnexæ, nevertheless, its value as a sign of the early diagnosis of pregnancy cannot be denied. In a series of two hundred patients, the sugar content of the blood, following the administration of one hundred grams of glucose on a fasting stomach and during rest in bed, increased, on an average, from 0.08 to 0.3 per cent. The urine was tested every ten minutes for one hour and at two successive intervals of thirty minutes. Of the women studied, thirty were not pregnant, one hundred and twenty were pregnant for three months, and fifty were in other stages of pregnancy. All of the women that were pregnant for less than three months showed pronounced glycosuria, whereas the glycosuria appeared only in sixty-six per cent. of the other pregnant women and only in one of the thirty nonpregnant women. Spontaneous glycosuria was found only in 0.75 per cent. of three hundred other pregnant women examined and the sugar content of the blood of the latter was within normal limits.

Treatment of Rheumatism With Thyroidine.—Santiago Libarona Brian (*Revista de la Asociacion Medica Argentina,* July, 1923) has ceased to prescribe sodium salicylate in the acute period of rheumatism, employing only thyrodine in daily increasing dosage, beginning with six centigrams and going up to eighteen centigrams at each injection in adults. Thyroidine thus administered in maximum doses gave rapid results except in nervous individuals where the drug increased the nervousness, made them irritable and caused sweating, thus preventing the continued use of large doses. Nevertheless even these cases ultimately responded to the thyroidine treatment.

Therapy of Chronic Arthritides.—Carl Reitter (*Wiener klinische Wochenschrift,* April 9, 1923), calls attention to the necessity of considering the joints less as a circumscribed and independent group of organs of a mechanical nature than as a coordinated portion of the organism, dependent on constitutional conditions. This applies particularly to the chronic polyarthritides and the predominant significance of the connective tissue in all the pathologic processes in the joints. In addition to the previous infections special investigation should be made concerning the endocrine relationships (the ovary, thyroid gland and others), and these usually call attention to a line of treatment that promises success.

Chondrodystrophy and Pregnancy.—E. Wehefritz (*Zentralblatt für Gynäkologie,* March 31, 1923) asserts that, according to the modern teachings of heredity, chondrodystrophy is hereditary and therefore the mother should be sterilized after delivery by Cæsarean section, especially in the delivery of a healthy child. If chondrodystrophy can be diagnosed in the fetus röntgenographically by the method of Warnekros during the sixth to the seventh month of pregnancy, interruption of the pregnancy is indicated.

In recommending an infant food —consider its nutritive value first

Cleanliness, digestibility, and palatability are also of importance, but without nutritive value any food would be useless as a body builder.

FOR the infant, breast milk furnishes all of the requirements mentioned. There is no need to seek further for a better food because no one has as yet been able to prepare a formula which can be considered anything other than a second choice.

As a breast milk substitute there is no better food for the infant than Eagle Brand Milk. For more than four years the largest child-feeding clinic in the history of the world has been maintained in the Near East, and Eagle Brand Milk has met every requirement for a complete milk food for the infants and older children throughout this period.

Reprints of clinical experiments with sweetened condensed milk will be sent upon request.

HACKENSACK, - - - - - - - NEW JERSEY, U. S. A.

Skin Affections of the Climacterium.—Robert Bauer (*Zentralblatt für Gynäkologie,* February 3, 1923) thinks that pruritus in the genital region or occurring diffusely over the body, even in the form of eczema, may be due to a disturbance of internal secretion and the decomposition of toxic products. The author was led to this conclusion by the results of successful organotherapy in several cases with ovarian preparations.

Cupping Glass Treatment of Chronic Gonorrhea in the Female.—Matzenauer and Hans Weitgasser (*Wiener klinische Wochenschrift,* November 30, 1922) report good results with the use of the usual Bier suction cup (without any indentation, so that it may be easily removed from the portio vaginalis), to which a thick glass tube about ten cm. long is attached. The suction is continued for fifteen minutes to one hour and after that a tampon with some antiseptic powder is introduced. This procedure causes the gonococci to disappear in a very short time in cases of uncomplicated cervical gonorrhea. It is contraindicated in all cases in which the uterus is the seat of an acute process.

Additional New Symptoms of Fissura Ani.—K. Svehla (*Monatsschrift für Kinderheilkunde,* March, 1923) asserts that the subjective symptoms of anal fissure may be variegated and even bizarre and so different from the symptoms usually mentioned that they may lead to a false diagnosis. He calls particular attention to: 1, general emaciation; 2, pains referred to different parts of the body, not excluding the teeth, but particularly localized in the region of the liver and cecum; 3, diarrheas alternating with constipation; 4, psychic excitability alternating with changes in disposition, particularly a bad disposition; 5, spasmodic attacks resembling, particularly, epilepsy. The observation of such symptoms leads to the view that the examination of the rectum is important even when the symptoms do not apparently originate in the rectum. Of the objective symptoms, not all are equally pronounced: the pain on defecation is not always present and bleeding during and after defecation does not occur in every case. A constant and never failing objective symptom of anal fissure is the intense pain which results from the digital examination of the rectum and traction on the mucosa of rectum. In children rectoscopy may be difficult and misleading as the fissure may be hidden in folds of rectal mucosa.

Treatment may be instituted from three directions: 1, correction of the anemia, as by cauterization of the fissure, but this is painful and leads to a cure very slowly; 2, the elimination of the occurrence of a marked muscular contraction to avoid anemia, as by forcible rupture of the sphincter; 3, the elimination of the pains as a cause of the reflex spasmodic contraction of the sphincter and the other results. For the latter purpose, the author as a rule gives calomel in divided doses (no more than 0.03 gm. a dose); if three doses are not followed by stools, an enema is given. As soon as it is believed that no more evacuations will occur, a cocaine suppository, 0.1 gm., is inserted into the rectum during the afternoon or evening. On the next morning a second cocaine suppository is inserted. The procedure of the preceding day is repeated at night. In most cases ten suppositories will not be required.

New Publications Received.

ENDOCRINE DISEASES. Including Their Diagnosis and Treatment. By Wilhelm Falta. Translated by Milton K. Meyers. Third Edition. Philadelphia: P. Blakiston's Son & Co., 1923.

"When Winter Comes"

—a great many patients—especially the weak and debilitated—need to be fortified against the depressing effects of cold weather, and for this purpose probably no remedy is more widely employed by physicians of experience than

Gray's Glycerine Tonic Comp.

If its use is started early, as soon as the chilly days of Fall begin, this tonic reconstructive will, in the great majority of cases, promptly raise the functional activity of vital organs, and as a logical sequence, produce a marked gain in the defensive powers of the body against germ attack.

Gray's Glycerine Tonic Comp. will thus enable the practitioner to carry many a patient through the Winter with gratifying freedom from the colds, coughs and catarrhal affections in general, that make this period so trying and dangerous to those susceptible to the acute infections.

Valentine's Meat-Juice

For **Quieting** the **Irritable Stomach** in **Pregnancy**, for **Rapidly Restoring** the **Vital Forces** in **Hemorrhage**, for **Sustaining** and **Strengthening** in **Long** and **Exhausting Labor**, **Valentine's Meat-Juice** is extensively employed in

Obstetrical Practice.

Dr. E. Duloroy, *Physician Accoucher to the International Hospital, Paris, France:* "A young accouchée, in a very weak condition and suffering from stomach trouble, could retain no food, but was able to assimilate VALENTINE'S MEAT-JUICE given at first in small doses. An improvement was quickly visible, the patient recovered her strength and is today in good health."

Dr. Javier Ortis y Ferrer, *Physician to the Municipal Charity of Madrid, Spain:* "VALENTINE'S MEAT-JUICE has given the happiest results in cases of debility and in the asthenia produced by operations of confinements. In some cases of Tuberculosis it restored exhausted strength, and in every case where organic exhaustion manifested itself as an effect of disease."

Physicians are invited to send for brochures containing clinical reports.

For sale by American and European Chemists and Druggists.

VALENTINE'S
PREPARATION
NUTRIO PRIMUS
MEAT JUICE.
The result of an original Process of Preparing Meat, and extracting its Juice, by which the elements of nutrition are obtained in a state, ready for immediate absorption.
DIRECTIONS-Dissolve one teaspoonful of the Preparation in two or three tablespoonfuls of cold or warm water. The use of boiling water changes the character of the preparation.

Miscellany.

Extrasensorial Channels of Knowledge.—Charles Richet (*Lancet,* September 8, 1923) endeavors to show by means of experiments that a knowledge of reality may be obtained through other means than that of the ordinary five senses. He proposes the new name of metapsychics for this new science and divides it into two separate groups: 1, subjective metapsychics, which has reference only to the phenomena of consciousness, and 2, objective metapsychics, which has reference to the external phenomena which are not explainable by the ordinary laws of mechanics. Four explanations are offered: 1, defective or fraudulent observations, but even of these fifty per cent. cannot be impugned; 2, chance, which cannot explain everything; 3, the spiritualistic theory of the return of the astral body of a dead person is untenable; and 4, what is neither an explanation nor an hypothesis, but a simple enunciation of the fact, which is confirmed in a startling manner by experiment, that the occurrences of the external world, even when they do not affect our sense organs, can still influence our consciousness. The channels through which this occurs is unknown. Experimental data are of two kinds: 1, those observed in persons in the hypnotic state or in the so-called spiritualistic trance, and 2, those which have been observed in normal individuals. Both sets of experiments are equally valid and lead to the conclusion that, in addition to the ordinary sensation, there exists a mysterious hidden sensibility—a cryptesthesia.

Pyocyaneus Bacteriophages.—Sukeyasu Okuda (*Wiener klinische Wochenschrift,* September 6, 1923) states that as a result of his investigations the number of the laboratory strains of pyocyaneus, which contain the bacteriophages against this strain, have been increased. According to previous experiences it appears likely that at least all those strains of pyocyaneus which produce a dark discoloration of their nutrient medium, will have to be examined for the presence of bacteriophages. However, those strains which produce only a light discoloration, need not necessarily be free from bacteriophages. The very peculiar, rudimentary bacteriophages, which are recognized only by a change in the growth of the bacteriophage free strain "Herbert," will have to be given some consideration in the future, as the sensitiveness to heat in this case shows no insignificant fluctuations, which can be explained only partially by differences in concentration. The fact that the formation of bacteriophages, which are apparently very abundant in pyocyaneus, appear in almost typical formation in at least one strain of the Bacillus fluorescens liquefaciens (Basel) offers new evidence of the relationship of these two bacteria.

Pellagra.—B. W. Page (*New Orleans Medical and Surgical Journal,* November, 1923) says that in the treatment of pellagra five grains of ichthyol in pills or peppermint water, or 1/100 of a grain of copper arsenite three or four times a day gives the best results. Other drugs are occasionally indicated as various symptoms arise. An immunity or cure seems to be established in most cases within a few weeks.

Thermal Death Point of the Tubercle Bacillus in Milk, with Special Reference to Its Application in Practical Pasteurization.—F. W. Campbell-Brown (*Lancet,* August 18, 1923), by using twenty-five strains of the tubercle bacillus, showed that no wide differences exist in the thermal death point. The death point of this organism is practically similar for human and bovine types. The previous wide variations in results have been due to too little care in carrying out the experiments, and to the fact that previously the lesions caused in test animals had not always been given sufficient time to develop and be accurately diagnosed. If a temperature of 60° C. be used, it requires twenty minutes' exposure to this degree of heat to prevent milk so treated carrying infection to the guineapig. If a temperature of 70° C. be used, it requires five minutes' exposure to insure the same results. Of these two combinations of time and temperature factors, the former excels the latter, when the food value of the treated milk is also considered. The author is of the opinion that, until bovine tuberculosis can be stamped out at its source—namely, in the ox—proper pasteurization of milk is the only safe method of rendering milk safe as a diet.

Effect of a Normal Meal Upon the Blood Sugar Level in Health and in Certain Conditions of Disease.—I. C. Brill (*Journal of Laboratory and Clinical Medicine,* August, 1923) has made a comparative study of the effects of an average normal breakfast upon the blood sugar content in normal individuals and in various chronic conditions in which the food tolerance is known to be affected. The method is suggested as one to serve as a true food tolerance test, and therefore all the food elements should be represented in the test meal, which included the usual breakfast foods, bread, butter, cereals, eggs, sugar, coffee and cream, amounting to approximately one hundred grams of carbohydrate, twenty-six grams of protein, twenty-seven grams of fats, and 760 calories. In all the cases tried, the curve corresponds very closely to that obtained with the Janney glucose tolerance test. The method suggested is preferable to the glucose tolerance test in that it is simpler, is more agreeable to the patient, and it avoids the danger of overtaxing a weakened function by a large quantity of pure glucose.

Studies of Living Human Blood Cells.—Florence R. Sabin (*Bulletin of the Johns Hopkins Hospital,* September, 1923) describes a technic for studying living blood cells which is simple and readily applicable to the study of clinical cases. The very marked gain in the use of the supravital method for the study of the white cells is the possibility of distinguishing cells which have been markedly stimulated to activity from cells which are degenerating. The second great advantage is the ability to distinguish the old and dying cells so as to complete the life cycle of each of the three types of white cells. From the study of the white blood cells presented, Sabin has shown that there is much evidence to favor the view that the large mononuclear cell is the young form of the monocytic strain and that the large lymphocyte is the young stage of the lymphocytes.

Bowel Torpor in the Elderly

is usually the result of a progressive atony of the bowel, with a gradual decrease of the natural mucus and other secretions. The loss of moisture dries the feces and interferes with their free and easy passage. Under such conditions

INTEROL

serves as a safe and efficient substitute for the physiologic secretions. Following its systematic use, the bowel contents are kept soft, the intestinal canal—especially the large intestine—is adequately lubricated, and the feces are passed along and evacuated in due time without straining, pain, or discomfort.

INTEROL thus constitutes an ideal medium for the relief of bowel torpor in patients of advanced age.

DIRECTIONS:

In treating the elderly, begin with a tablespoonful morning and night on an empty stomach, increasing or decreasing as conditions require.

Sample and Interol brochure on request.

HACKENSACK, . - - - - - - - NEW JERSEY, U. S. A.

Rôle of the Lymphatics in the Absorption of Bile Pigment From the Liver in Early Obstructive Jaundice.—William Bloom (*Bulletin of the Johns Hopkins Hospital,* September, 1923) performed a series of experiments in which both kidneys were removed from a dog in order to prevent any of the bile pigment from being excreted into the urine. The common bile duct was then double ligated and sectioned. The gallbladder was prevented from functioning either by complete extirpation or by ligation of the cystic duct in order to eliminate the variations in time of appearance of bile in the blood, which must obviously occur in experiments in which the varying size and degree of distention of the gallbladder are not controlled. A positive test for bilirubin was obtained in the lymph stream while the blood was still pigment free. The experiments show that the fine intercellular bile capillaries are not ruptured before there is an appreciable bilirubinemia consequent to the occlusion of the common duct. The blood serum of dogs in the first day or two after the blocking of the ductus choledochus gives the indirect Van den Bergh reaction, and in so far renders doubtful the interpretation of the indirect test when actual tissue icterus is not present. After the scleræ are definitely icteric, the direct test is always given. It appears that the removal of bile pigment from the liver in the earliest stages of mechanical jaundice is entirely by the lymph stream and not by the blood stream.

Carbon Tetrachloride in Pharmacology and Therapeutics.—R. N. Chopra and J. Borland McVail (*Indian Medical Gazette,* October, 1923) say that carbon tetrachloride is the most efficient anthelmintic known for hookworm. It is of little value in Ascaris infections and of no value against Tænia. The toxic dose of one to four c. c. to the kilo of body weight is far in excess of the therapeutic total dose of five c. c., i. e., 0.13 c. c. to the kilo, which is given as an anthelmintic to a normal individual weighing sixty-five kilos. Owing to its low solubility and volatility and consequently slow rate of diffusion, only small quantities are absorbed into the circulation. Large quantities can therefore be introduced into the alimentary canal without untoward effects. When given in medicinal doses and with a purge to persons organically sound it is safe, provided the drug is pure, is swallowed, and does not enter the larynx. Carbon tetrachloride itself and its vapor are irritating, and if brought into contact with the mucous membrane of the respiratory tract in any concentration may produce a reflex stoppage of respiration and later a stoppage of the heart and death. Therefore, it must not be forced on struggling children. The great contraindication is a liver with impaired function, such as is caused by alcoholism. The liver appears to retain a large proportion of the small quantity which is absorbed and so protects the vital organs from injury. The presence of heavy round worm infection may also be a contraindication. Large and toxic doses of this drug, whether single or divided, have a damaging effect on the liver parenchyma. With therapeutic doses the damage, if any, is temporary and unimportant. The action of the drug on voluntary and involuntary muscle is depressant. In medicinal doses it is slightly laxative and has no abortifacient action.

Effect of the Intravenous Administration of Mercurochrome on the Bacteriostatic Action of Blood.—J. H. Hill and J. A. C. Colston (*Bulletin of the Johns Hopkins Hospital,* November, 1923) report that following the intravenous administration of mercurochrome, the bacteriostatic action of the blood against Bacillus coli is increased. This increase appears to be greatest from fifteen to forty-five minutes after injection, after which it rapidly disappears.

Action of the Pylorus and First Part of the Duodenum.—Theodor Bársony (*Wiener klinische Wochenschrift,* September 6, 1923) found that in addition to opening and closing, the pyloric valve undergoes a movement which is the result of the antral and bulbar pressure, respectively, and results in a corresponding protrusion. This movement can be observed only in a few cases and then only during a certain stage of the examination. Inasmuch as the contraction of the bulb lasts only a short time and the systole of the antrum continues for a long time, the antral pressure determines the character of the form of the first part of the duodenum.

Following the Acute Infections

prompt and uncomplicated recovery almost always calls for the systematic use of an efficient restorative tonic—a preparation that will place the least possible burden on the digestive and assimilative functions of the body, but will at the same time supply the support so urgently needed by weakened and exhausted tissues.

The constantly increasing number of medical men that have come to rely on

Gray's Glycerine Tonic Comp.

as a reconstructive tonic, tell beyond all question of its efficiency for the foregoing purposes. Under its use, functional activity is promptly increased, the nutrition is rapidly improved, and the defensive forces of the body are substantially raised.

Gray's Glycerine Tonic Comp. is thus recognized by the busy practitioner as a body-builder to which he can "pin his faith" as a dependable means of promoting convalescence and hastening recovery.

A trial of this reliable tonic will show its exceptional value following the acute infections prevalent at this season of the year.

Miscellany.

Compound Craniocerebral Injuries.—Samuel C. Harvey (*Boston Medical and Surgical Journal,* December 6, 1923) thus describes the operative procedure: The wound in the scalp is lightly packed with gauze saturated with alcohol or tincture of iodine. The entire scalp is then moistened with green soap and shaved without the preliminary use of clippers or scissors. This removes, if carefully done, in the most effectual manner the gross dirt and blood, and a scrub with green soap followed by alcohol and bichloride solution completes the preparation. The original tampon in the wound is now removed and replaced with a second of the same nature. The wound in the scalp is excised *en bloc* with the knife and incisions made, curvilinear or of the "Isle of Mann" type in such a fashion as to enable one to lay back the scalp with a wide exposure of the underlying bone. The portion of this which may have been contaminated is carefully kept away from and multiple perforations are made about it with the Doyen or Hudson burr. These are connected by means of the De Vilbiss or Montenevesi forceps and this area of bone lifted out *en bloc*. It is extremely important that this incision be placed in the bone outside of the possible area of gross contamination and over intact dura. It is necessary to bear in mind at this point that the primary requisite is a procedure which is life saving and that the cosmetic result is relatively unimportant. It is also well to recall that control of intracranial bleeding is simple with adequate exposure, but wellnigh impossible otherwise. Therefore a sufficiently ample area of bone should be removed in order to insure the fulfilment of these requisites. Depressed bone with adequate blood supply may be elevated, but all free fragments of bone in which the blood supply is gone and which lie extradural, should be gently lifted out and removed, inasmuch as this is neither the time nor the place to attempt even autogenous bonegrafts.

The care of the lacerated dura is governed by the fact that it early becomes adherent to the subjacent meninges and such adhesions should be disturbed as little as is possible. The edges rarely need excision except where there are free tags hanging in the wound. When the delay has been short and the approach free from contamination, it may be advisable to enlarge a dural perforation in order to evacuate more thoroughly a subjacent blood clot or the pulped brain tissue; but the occasion is rare when this procedure is expedient.

The treatment of the damaged cortex is directed toward the removal of dirt and devitalized tissue, and foreign bodies such as indriven bone or missiles. The second should not be searched for until the first has been accomplished, for the exploration should be carried out through as clean a wound as possible. The pulped and contaminated brain may often be extruded by having the conscious patient gently strain or cough. It is then washed away with a jet of Ringer's solution, which should be kept playing in the wound throughout this stage of the procedure. Many times by this simple method most of the débris can be removed and the gentle exploration of the cortex with a fine soft rubber catheter through which the salt solution is flowing will complete the cleansing. At the same time this will often enable one to locate indriven fragments of bone or a foreign body. These should be very gently lifted out with fine forceps and this method of examination carried on until nothing more can be found. Only as a last resort should the bare finger be introduced, and then with exceeding gentleness. The operator must be certain that he does not increase the contamination and laceration of the cortex by his own manipulations. His every move should be purposeful. The closure is effected by the careful suture of the scalp in two layers, so carefully done that there can be no leakage and so accurately approximated that healing will be *per primam.* A small rubber tissue wick, to be removed in twenty-four to forty-eight hours, is placed at one angle and serves two purposes,—the one to give exit to the oozing of the immediate postoperative period, the other to provide for the early recognition of infection, for on removal a study of a stained smear is made.

The first evidence of infection must be countered by laying the wound widely open, and adopting treatment as for a fungus cerebri. No gauze must come in contact with the brain substance. It is covered by protective tissue which is removed every twenty-four hours and the wound gently washed with a stream of Ringer's solution. No pressure must be allowed on the herniating cortex and the dressing is built up about it with a "doughnut" so that there can be no compression. By these simple measures at least fifty per cent. of the infected wounds will recover.

Home Disinfection and the Control of Scarlet Fever.—K. Simpson (*Lancet,* September 1, 1923) asserts that home disinfection at best is little more than a formal, much less than a complete proceeding, and consequently can neither reasonably prevent subsequent infection occurring in an already apparently disinfected home among susceptibles—susceptibles of school age being meanwhile excluded from school—nor the subsequent spread of the disease once an outbreak has occurred, which is almost entirely dependent on carriers and school attendance, rather than fomites, leaving out of account for the present sporadic cases met with from time to time in the adult. The author is strongly of the opinion that much of the funds at present spent upon disinfection could be more usefully employed in creating a healthier state of the nasopharynx of the school child by directing greater precision to the examination and treatment of all such defects discovered upon routine medical inspection of school children, by preventing overcrowding in schools, and by the prompt closure of all schools or school departments—public, private and Sunday—in any area threatened with an outbreak of scarlet fever. So far as home disinfection is required after the patient's removal, blankets, etc., from the home used in conveying him to the hospital, should as a matter of course be disinfected before their return, while the further disinfection of the home need only be directed to an effort on the part of the occupants to spring cleaning their infected room with the aid of sunlight, soap and water. The usual method of home disinfection may, however, also be carried out.

In recommending an infant food —consider its nutritive value first

Cleanliness, digestibility, and palatability are also of importance, but without nutritive value any food would be useless as a body builder.

FOR the infant, breast milk furnishes all of the requirements mentioned. There is no need to seek further for a better food because no one has as yet been able to prepare a formula which can be considered anything other than a second choice.

As a breast milk substitute there is no better food for the infant than Eagle Brand Milk. For more than four years the largest child-feeding clinic in the history of the world has been maintained in the Near East, and Eagle Brand Milk has met every requirement for a complete milk food for the infants and older children throughout this period.

Reprints of clinical experiments with sweetened condensed milk will be sent upon request.

ACKENSACK, . - - - - - NEW JERSEY, U. S. A.

Scarlet Fever as a Reaction of Hypersensitiveness to Streptococcus Protein.—Leverett D. Bristol (*American Journal of the Medical Sciences,* December, 1923) presents an interesting study of scarlet fever and suggests, 1, that scarlet fever is a reaction of specific hypersensitiveness to streptococcus protein, and 2, that it is a compound condition, involving primarily a local streptococcic infection, usually of the throat but frequently of an accidental or operative wound, burns, or associated with the puerperium, and secondarily a streptococcus protein intoxication in those who are hypersensitive. On the basis of such a theory it seems probable that the prevention and treatment of scarlet fever may depend on two factors; 1. The control of the streptococcus *per se* through adequate isolation and concurrent and terminal disinfection of all cases, including not only frank scarlet fever, but also all other virulent streptococcus diseases, as well as the isolation and treatment of all streptococcus carriers, and proper attention to milk and other possible vehicles of streptococcic infection. 2. The desensitization of individuals who by cutaneous tests are shown to be hypersensitive to streptococcus protein, either by specific (vaccines or antisera) or nonspecific (protein or serum) methods of treatment; and adequate attention to local sites of streptococcic infection, such as the throat, to reduce to a minimum the possible absorption of streptococcus protein.

Tangential Percussion.—L. Karczag (*Wiener klinische Wochenschrift,* August 30, 1923) states that the indirect tangential percussion blow and not the sagittal percussion is the best method of percussion for the determination and limitation of substernal areas of diminished resonance. The finger is bent at a right angle to the fingertip and threshold percussion is practised on the second finger, tangential to the area of percussion. The advantages of this method are that the area of oscillation is reduced as well as the oscillations themselves and there is also a diminution of the threshold value. It is particularly useful in determining the limitations of substernal areas of diminished resonance because it eliminates the tone of the sternum itself as much as possible. Percussion is made either upon the second phalanx of the middle finger in the Plesch position of the hand or upon a pleximeter about eight centimeters long and five to eight millimetres thick, made of ivory or ebony. The author distinguishes between manubrial, corporal, and xiphoid dullness.

Isoamyl Ethyl Barbituric Acid—An Anesthetic Without Influence on Blood Sugar Regulation.—Irvine H. Page (*Journal of Laboratory and Clinical Medicine,* December, 1923) found that isoamylethylbarbituric acid, in amounts sufficient to produce surgical anesthesia, has little or no effect upon the blood sugar, and is superior to barbital, isopropylethylbarbituric acid, trichlorotertiary butyl alcohol and urethane for blood sugar investigation. Animals under the influence of this anesthetic show normal responses to splanchnic stimulation, and with it the usual hyperglycemia following hemorrhage occurs. Insulin produced a uniform decrease in blood sugar in animals under this anesthetic, probably due to the fact that the nervous factor in glycogenolysis is minimized.

Ischiorectal and Other Abscesses.—J. P. Lockhart-Mummery (*Clinical Journal,* December 5, 1923) asserts that an ischiorectal abscess may be opened in the following manner with less danger than usual of formation of a fistula. The abscess is opened with a knife by a crucial incision in the usual way and the pus allowed to flow out. The skin covering, or forming, the outer wall of the abscess is then completely cut away so as to leave a large opening of an inch or more in diameter, the interior of the abscess being left entirely alone and untouched. A large flat dressing of moist antiseptic gauze is applied all over the parts and covered with a protective, so as to keep it moist and prevent it sticking to the edges of the wound and interfering with drainage. The pad should be large enough to absorb all the discharge for at least twelve hours. The patient should be nursed lying on his back as much as possible, so that the pressure is towards the opening in the abscess. When the dressing is changed it will be found that the abscess cavity has completely vanished, and that there is only a flat shallow ulcer, which may take ten days or a fortnight to heal, but does not result in a fistula once in twenty times.

Valentine's Meat-Juice

In **Diarrhoea, Dysentery** and **Cholera Infantum,** in the **Wasting** and **Febrile Diseases** of **Children,** and in the treatment of **Weak Babies,** the **Ease** of **Assimilation** and **Power** of **Valentine's Meat-Juice** to **Restore** and **Strengthen** has been demonstrated in Hospitals for Children.

VALENTINE'S PREPARATION
NUTRIO FERMIE
MEAT JUICE.
The result of an original Process of Preparing Meat, and extracting its Juice, by which the elements of nutrition are obtained in a state, ready for immediate absorption.
DIRECTIONS—Dissolve one teaspoonful of the Preparation in two or three tablespoonfuls of cold or warm water. The use of boiling water changes the character of the preparation.

Diseases of Children.

W. T. Watt, M. D., *Director Imperial Medical College, Tientsin, China:* "In cases of Infantile Diarrhœa, which weakens and debilitates a child rapidly, I have found VALENTINE'S MEAT-JUICE a great stimulant and quick restorative of vitality. Three years ago when an epidemic broke out in Tientsin, I ordered my staff to try your MEAT-JUICE, which justified all expectations, having been satisfactory to patients and physicians alike."

Dr. Calatraveno, *Late Physician of the Children's Hospital, Madrid, Spain:* "I have employed VALENTINE'S MEAT-JUICE most successfully in cases of convalescence from infectious diseases, and it is especially beneficial for children suffering from urinary weakness caused by extreme debility, as in every case it acted remarkably in restoring their strength with notable rapidity."

Physicians are invited to send for brochures containing clinical reports

Miscellany.

Effect of Histamine on the Human Gastric Secretion.—Alister R. Matheson and Sydney E. Ammon (*Lancet,* March 10, 1923) found that histamine given subcutaneously in small doses excites a flow of gastric juice in man. The peptic activity increases after the injection and reaches its maximum usually in about five to fifteen minutes. Both total and free hydrochloric acid increase and attain their maxima shortly after the pepsin maximum is registered. The secretory rate follows a similar course, and usually attains its maximum last of all. The dose employed by the authors to evoke gastric secretion does not produce any harmful gastric or general disturbance. This being the case, it seems possible that histamine may be employed as a means of investigating the state of gastric secretory function and perhaps as a therapeutic agent.

Study of Yeasts Found in Sputum of Patients with Asthma and Chronic Bronchitis.—Edward Steinfield (*Journal of Laboratory and Clinical Medicine,* August, 1923) found yeasts belonging to the genera Monilia endomyces and cryptococcus in large numbers in the sputum of patients with asthma and chronic bronchitis. On the basis of biochemical reactions, some of these were comparable to the yeasts, particularly Monilia, found in cases of bronchomycosis described by Castellani. Production of eosinophilia in the peritoneal exudate and blood of guineapigs after intraperitoneal injections was noted as a constant feature. The patients from whom these cultures were isolated did well when treated with iodides in the dosage of about 2 gm. a day or more. The injections of vaccines made from suspension of spores was given a tentative trial with fair results, such as are often noted with the use of bacterial vaccines.

Uric Acid in the Blood.—The clinical importance of ascertaining the amount of uric acid in the blood has recently been demonstrated by Professor Jeanbrau, of the Faculty of Medicine of Montpellier, and his coworkers, Dr. Cristol and Dr. Nikolitch. There are four factors that provoke pathological uricemia, according to these observers, who admit gram 0.03 to gram 0.05 to the thousand c.c. as the extremes of normal uricemia.

The first factor is renal. A nephritic kidney, impermeable to urea, is likewise impermeable to uric acid. But the increase of the percentage of the uric acid in the blood precedes that of urea and the alarm uricemia precedes the alarm azotemia of Widal. In some cases of unquestioned azotemic nephritis these observers have noted hyperuricemia, but the patients had high blood pressure, so that the circulatory factor compensated the renal factor.

The second factor is circulatory. In patients with a perfectly compensated cardiopathy—clinically, high blood pressure—the hyperuricemia is insignificant, while, when the equilibrium of the circulation is broken, hyperuricemia becomes manifest, and just as uric acid is the first nitrogenous compound retained in the case of renal impermeability, so it is the first to be retained in the blood when diuresis decreases on account of a disturbed equilibrium of the blood pressure.

The third factor is mechanical. The research for uricemia in prostatic and stricture cases—twenty-five patients in all—revealed the fact that this class of patients usually presented hyperuricemia, likewise hyperazotemia, hence a high percentage of urea in the blood is a temporary contraindication for prostatectomy. However, even in cases where the blood urea is not above gram 0.50 to the thousand c.c., hyperuricemia is manifest. Here again, uric acid is the first nitrogen compound retained. This increase of uricemia is the result of vesical retention and distention which offer a mechanical obstacle to renal secretion. Cystostomy causes the renal congestion to subside and an almost normal excretion of urine ensues. These observers found that uricemia remains normal when the lesion is unilateral in surgical affections of the upper urinary tract, but hyperuricemia is generally present in bilateral renal tuberculosis and pyelonephritis. A mild hyperuricemia even is the first evidence of functional bankruptcy of the opposite kidney.

The fourth and last factor is that of the tissues. Hyperuricemia is manifest in cachectic subjects, in which destruction of tissue is active, such as cancer, tuberculosis and other serious infectious processes. In this case, the uricemia is endogenous, while the three factors are exogenous. These findings have appeared to me of sufficient clinical importance to give somewhat in detail.

A New Organic Compound With Powerful Germicidal Properties.—George W. Raiziss and M. Severac (*Journal of Laboratory and Clinical Medicine,* November, 1923) describe a new mercury compound which they call metaphen which is a powerful germicidal substance, particularly against staphylococci. It has the following properties: a comparatively high bichloride of mercury index; practically nonirritating to the skin or mucous membranes; low toxicity when administered intramuscularly; powerful spirocheticide; does not tarnish surgical instruments, and does not precipitate proteins in as high concentration as 1:200, while the maximum concentration for all practical purposes should not exceed 1:1000. The authors recommend its use because of its high destructive effect upon bacilli, and its many favorable biologic properties.

Aftereffects of Certain Industrial Injuries and Their Treatment by X Rays.—Reginald A. Morrell (*British Medical Journal,* September 15, 1923) states that the clinical improvement after the use of x rays is manifested, 1, by the relief of pain when a nerve was being strangulated by cicatricial tissue in cases of superficial scars and in certain cases of neuromata in amputation stumps; 2, by greater and more rapidly secured freedom of movement in such a joint as the shoulder after prolonged suppuration and extensive operations in its neighborhood; 3, by a greater range of action in cases of transplanted tendons for injuries of the musculospiral nerve, and 4, by improvement in peripheral circulation where the brachial vessels were being constricted by scar tissue following gunshot wounds. Radiotherapy is indicated in injuries of the tendons of the wrist or fingers after primary or secondary suture, extensive lacerated wounds or burns of muscle, tenosynovitis, Dupuytren's contracture, and keloids.

An Effective Remedy *for* Nervous Sleepless Patients

Neuronidia

Palatable Well-Tolerated Reliable

Allaying Restlessness and Producing Refreshing Sleep

Especially indicated in insomnia from mental strain, neurasthenia and other neuroses; also an excellent sedative in sea-sickness.

HACKENSACK, . - - - - NEW JERSEY, U. S. A.

The Problem of Overcrowding in London Hospitals.—Mr. E. W. Morris, House Governor of the London Hospital, Whitechapel, speaking in London recently on The Future of the Voluntary and Municipal Hospitals, advocated the giving of power to the voluntary hospitals to make use of the facilities afforded by Poor Law Infirmaries. There were 117 hospitals in London and 835 in the rest of Great Britain, with a total between them of 52,194 beds. The taint of the Poor Law made the infirmaries unpopular with the poor, but in these Poor Law infirmaries there were 92,000 beds, 30,000 of which were empty during the summer months and 20,000 in the winter. It was reasonable to try to devise a means whereby these unused beds could be utilized by persuading the sick poor to make use of the infirmary as well as the hospital. He suggested that the hospitals should have power to send patients to the infirmaries on some special terms. The hospitals were now taking some hundreds of cases which would go to the infirmaries but for the existence of the hospitals. The hospitals could ease the burden on their beds by declining to admit accident cases until they had cleared their waiting lists, thus compelling the emergency cases to go to the infirmary. It could be arranged that cases sent from the hospitals should be grouped together in the infirmary and not be placed under the stigma of pauperism. Such patients would wear their own clothes and be registered in special books. The hospital could not pay in cash but it could in other ways. The consultants would visit the infirmary and qualified hospital students would be called upon to act as house surgeons and physicians under the infirmary medical officers. There could be an interchange of patients.

Preschool Education.—At a congress on education, held recently in London, Miss Margaret McMillan, president of the Nursery Schools Association, discussed Preschool Education. She said that the Nursery Schools Association stood for the help of the very young school element that had never been catered to before. Its mission was to be flexible, and to adapt itself to rapidly changing conditions and environment. The nursery school was an open air school and this was an important feature from the point of view of the child. Eighty-five per cent. of the children who entered these schools suffered from rickets and were tortured by fear, but the schools had saved them from both. The sunlight and fresh air had saved them from rickets, from tuberculosis and from deformity. The association's proposal was that new nursery schools should be started where they were most needed, in the crowded alleys of our great cities. In the Deptford Nursery School, of which Miss McMillan was the head, they had two hundred and fifty little children under the age of five years. It had been feared at first by medical officers and others that it would be dangerous to gather so many children together in one place, but experience had proved these fears unfounded, and, whereas, it had been the practice before the days of the nursery school to close all schools during an epidemic, the method of those in charge of nursery schools was to keep them open because there they could nourish the children and maintain their bodily strength. It was their plan to erect cheap open shelters for the children and not to confine the temple of the human soul within stone walls. Some of the schools had as many as ten open air structures and experience had demonstrated that the most suitable number of children for each shelter was thirty-five. In its work the nursery school was doing a great service, not only to the child but to the neighborhood. It had the function of a people's garden or recreation ground. It was an ideal place for the parents to go, and especially for young mothers. There they could look not only on blooming flowers and green patches, but they could look upon cultivated blossoms of humanity which were their own children. It was a city of refuge from the streets and narrow ways where the children's lives were threatened. What kind of life, she asked, had those children in their slum houses? They saw their parents only infrequently and heard only rough voices. There were about a million little children in England under five years to be dealt with and not fewer than five hundred thousand were in desperate straits. From two hundred to three hundred nursery schools were needed within the next five years.

VALENTINE'S
PREPARATION
NUTRIO PERMIE
MEAT JUICE.
The result of an original Process of Preparing Meat, and extracting its Juice, by which the elements of nutrition are obtained in a state, ready for immediate absorption.
DIRECTIONS-Dissolve one teaspoonful of the Preparation in two or three tablespoonfuls of cold or warm water. The use of boiling water changes the character of the preparation.

Miscellany.

Bodily Build a Clue to Disease.—Diagnosis of disease from the physical build of the patient may become a reality if the conclusions reached by Dr. George Draper, Dr. Halbert L. Dunn, and David Seegal, of the Presbyterian Hospital, New York, become generally confirmed. The "consumptive build" or the "bilious countenance" may be accepted as scientific realities.

Measurements made of fifty patients with gallbladder disease, and of thirty-nine patients with ulcers of the stomach or intestines have shown that those who suffer from one complaint have on the average a different physical build from those who suffer from the other. The diagnoses in all these cases were confirmed at operation. About eighty-five separate measurements were made on each individual.

Gallbladder patients were generally heavier for their height than those afflicted with ulcer, had greater chest depth, a wider and squarer upper jaw, and showed other marked differences. The method offers confirmatory evidence in cases of doubtful diagnosis.

The physicians who made these investigations do not believe that a given physiological form "in itself predisposes to or actually causes disease," but merely that physical features express inherited influences and predispositions. Aside from their value in finding out what is the matter with sick people, these measurements, made upon well persons, will be a guide to them as to what diseases they have particular reason to guard against.

These first reported scientific measurements were made at the new Constitution Clinic of the Presbyterian Hospital, which has been established for the purpose of finding out the relations between the bodily structure, the body functions, the mental processes, and immunity and susceptibility to disease.

Botulism Easily Prevented.—Fatalities from botulinus poisoning resulting from eating home canned foods, such as recently occurred in a Pacific Coast State, may be prevented beyond reasonable doubt by two simple precautions, officials of the Public Health Service say. These precautions are, first, the rejection of all canned goods which on opening look or smell spoiled or tainted in the least degree; and second, the reheating to the boiling point of all canned goods before serving. It is not safe to test doubtful cans by tasting their contents before heating, as fatal cases of poisoning have occurred from this practice. The heating should be thorough, all parts of the contents of the can being brought to the boiling point. Unless one wants to risk the lives of the fowls, apparently spoiled goods should not be fed to the chickens, since whole flocks have been killed in this way.

While, according to the Public Health Service, botulinus poisoning is a rare disease in proportion to the millions of cans of food packed, it is highly dangerous to eat any such food which appears to be in the slightest degree spoiled. Botulism is very rare east of the Pacific Coast States, in which outbreaks are much more frequent, the bacteria being apparently more common in the soil of that region. Acid vegetables and fruits which are thoroughly cooked before canning are safest. The greater number of fatalities have occurred from eating canned string beans, spinach, or corn; and more deaths have resulted from eating home canned products than those which are commercially packed.

Great Portuguese Library Opened in Washington.—The third largest library of Portuguese literature, and especially of that produced in Brazil concerning the history and development of that country, has just been opened in Washington. It contians forty thousand volumes and is the gift of Dr. Manoel De Olivera Lima to the Catholic University of America. Dr. Lima is a Brazilian and was for many years in the diplomatic service of his country. The library was collected during a period of forty years and contains many rare works, which are not to be had in any library of Portugal or Brazil. The collection, which is surpassed only by one in Lisbon and one in Rio Janeiro, is valued at $500,000. It contains also many rare prints and engravings and will eventually be housed in a building at the university to be erected solely for that purpose.

Lowly Worm's Track Preserved One Hundred Million Years.—Among the humblest of all living creatures is the sandworm. Yet there was once a family of sandworms in Sweden which made so fine a record of its wanderings that it has been preserved a hundred million years. This has been brought to light through the discoveries, just made, of various fossils of the Cambrian period, the earliest period of the Paleozoic age, at Narke, in the central part of Sweden. The worm tracks, known as arenicolies, consist of tubelike forms in the rocks, which are believed to have been left by the passage of worms through sand which afterwards became petrified. Dr. Westergardh, one of the state geologists, who has examined these finds, reports that, while similar fossils have previously been discovered in Sweden, these are particularly valuable because of the unusually fine preservation. He fixes the age as about one hundred million years.

New X Ray Apparatus Shows Anatomical Structure of Metals.—The development of an instrument that makes possible the investigation of the internal atomic structure of any metal or other substance has been made by Dr. S. J. M. Allen, of the University of Cincinnati, who is a research associate of the Carnegie Institution's Department of Terrestrial Magnetism, and is now working in the Cavendish Laboratory of Cambridge University under Sir E. Rutherford. Previous methods of x ray analysis have required that the substances to be examined should be in the shape of crystals or at least that the material be finely powdered. Dr. Allen's new apparatus allows the inspection of a piece of material in its natural commercial state without destroying its properties in any way. X rays are directed on the metal studied and the reflected rays are thrown on a photographic plate through the cracks in a series of very closely spaced lead plates which prevent all rays except those desired from reaching the negative. Although application to commercial testing has yet to be worked out, it is declared that the new process is likely to prove of great value in testing all sorts of materials.

In recommending an infant food —consider its nutritive value first

Cleanliness, digestibility, and palatability are also of importance, but without nutritive value any food would be useless as a body builder.

FOR the infant, breast milk furnishes all of the requirements mentioned. There is no need to seek further for a better food because no one has as yet been able to prepare a formula which can be considered anything other than a second choice.

As a breast milk substitute there is no better food for the infant than Eagle Brand Milk. For more than four years the largest child-feeding clinic in the history of the world has been maintained in the Near East, and Eagle Brand Milk has met every requirement for a complete milk food for the infants and older children throughout this period.

Reprints of clinical experiments with sweetened condensed milk will be sent upon request.

HACKENSACK, . - - - NEW JERSEY, U. S. A.

Long Distance Steam Gives Power and Heat.—A row of business buildings in Pittsfield, Mass., are now heated by the exhaust steam from a 750 kilowatt turbogenerator used by a local power company, says the *Engineering News-Record* in its current issue. The steam is conducted to the generator through what is believed to be the longest high pressure steam line in the world. It is 3,600 feet long, carries the steam at a pressure of 195 pounds, and is built partly under and partly above the ground. The pipe is eight inches in diameter and covered by three inches of insulation, consisting of two quarter inch layers of fireproof felt over which is a layer of eighty-five per cent. magnesia; over this is a protective jacket of heavy duck, while to waterproof the whole a three ply wrapping of roofing paper is used.

Frozen Nitrogen Cloud Makes the Sky Blue.—The blue color of the atmosphere is caused by a stratum of frozen, crystalline nitrogen in extremely high altitudes, according to theories put forward by Dr. L. Vegard. The aurora borealis and zodiacal light are attributed by him to the same cause. Dr. Vegard asserts that there is some point in the upper atmosphere where the temperature must fall as low as 350 degrees below zero Fahrenheit. If so, nitrogen, the main constituent of air, must freeze, even as snow is formed in an ordinary wintry atmosphere. The resulting nitrogen frost is likely to remain in a dispersed state. Dr. Vegard also assumes that it is electrically charged. Inasmuch as the atmosphere is shallower near the poles than at the equator, the air frost would approach the earth more closely in polar latitudes. More light disturbances would therefore occur in such regions. The presence of nitrogen at such great altitudes as must be necessary to get temperatures as low as 350 degrees below zero is accounted for by Dr. Vegard by the repellent effect of the electrical charges which these particles are assumed by him to carry. Temperatures at the highest levels at which observations have been made, or about twelve miles, have seldom been found lower than 85 degrees below zero, and the temperature shows no tendency to decline beyond that point. Dr. Vegard suggests that this outer shell of nitrogen frost cloud may act also as an envelope for the atmosphere and prevent it from diffusing into space.

Plant Veins Serve Them as Nerves.—The vascular bundles of plants have been found to serve a purpose similar to the nerves of animals, Prof. Henry H. Dixon, F.R.S., told an audience at a lecture in Dublin recently. These vascular bundles not only carry raw food material from the roots to the leaves but also transport the chemical messengers which take the place of nerve impulses, the speaker said. The similarity of distribution of the vascular bundles in plants and that of the nerves in animals was noticed long ago, but as the details of the two systems were worked out differences between the two became accentuated rather than the similarities; now the latter are receiving more attention. In both cases a stimulus given to one part of the body often causes a reaction in a different part. If the taproot of a plant be artificially deflected from the vertical, a stimulus is set up in a cell just behind the root tip, which results in a bending of the root at that point till it is again growing vertically downwards. Again, when the tip of a grass seedling is illuminated on one side a stimulus is transmitted thence downwards to the shaded part and causes curvature there.

It has been shown that the stimulus is propagated through some plants at a rate of ten to twenty millimetres a second. This speed, though slow compared with the velocity of transmission of stimuli along animal nerves, is fast among plants. Scientists are beginning to believe that the stimulus is conveyed by chemical messengers or hormones liberated by the stimulated part into the transpiration stream. In Professor Dixon's words: "Whatever the intimate mechanism of the system is, the subject of the transmission of stimuli through plant tissues offers a striking example of the swing of the scientific pendulum of scientific opinion. The view based upon superficial resemblances, that the vascular bundles are the nerves of plants, was long abandoned, but now we see there is clear evidence that they actually transmit stimuli from the sensory to the motor regions, and so perform the functions of nerves"; but there are very great differences in detail between the modes of action in the two cases.

Following the Acute Infections

prompt and uncomplicated recovery almost always calls for the systematic use of an efficient restorative tonic—a preparation that will place the least possible burden on the digestive and assimilative functions of the body, but will at the same time supply the support so urgently needed by weakened and exhausted tissues.

The constantly increasing number of medical men that have come to rely on

Gray's Glycerine Tonic Comp.

as a reconstructive tonic, tell beyond all question of its efficiency for the foregoing purposes. Under its use, functional activity is promptly increased, the nutrition is rapidly improved, and the defensive forces of the body are substantially raised.

Gray's Glycerine Tonic Comp. is thus recognized by the busy practitioner as a body-builder to which he can "pin his faith" as a dependable means of promoting convalescence and hastening recovery.

A trial of this reliable tonic will show its exceptional value following the acute infections prevalent at this season of the year.

Valentine's Meat-Juice

In **Gastric** and **Intestinal Troubles,** in **Febrile Conditions,** in **Wasting** and **Debilitating Diseases** and before and after **Surgical Operations** when the **Stomach** is **Rejecting Food** and it is **Essential** to **Conserve** the **Vital Forces, Valentine's Meat-Juice** demonstrates its **Ease** of **Assimilation** and **Power** to **Restore** and **Strengthen.**

In Hospital Practice.

P. McDonnell, *M. B. Hon. Surgeon, Lowestoft and North Suffolk Hospital, Lowestoft, England:* "We have found VALENTINE'S MEAT-JUICE invaluable in cases of shock and collapse of men who have been blown up in their ships by mines and torpedoes. Some of the patients have been severely injured, often for hours before admission here, and VALENTINE'S MEAT-JUICE has been the only food they could retain."

W. S. Tremaine, M. D., *Professor of Surgery, Niagara University; Consulting Surgeon Maternity, Emergency and St. Francis Hospitals, Buffalo, N. Y.:* "I have much pleasure in stating that I have used VALENTINE'S MEAT-JUICE for more than ten years and can testify to its excellence. I know that I have saved lives with it when every other form of nourishment was rejected. It is a most valuable preparation, and I constantly use it."

Physicians are invited to send for brochures containing clinical reports.

For sale by American and European Chemists and Druggists.

VALENTINE'S
PREPARATION
NUTRIO PRIMUS
MEAT JUICE.
The result of an original Process of Preparing Meat, and extracting its Juice, by which the elements of nutrition are obtained in a state, ready for immediate absorption.
DIRECTIONS-Dissolve one teaspoonful of the Preparation in two or three tablespoonfuls of cold or warm water. The use of boiling water changes the character of the preparation.

Miscellany.

Pellagra Prevented by Fresh Meat Diet.—Surgeons Joseph Goldberger and W. F. Tanner, of the United States Public Health Service, in a report on the treatment and prevention of this disease, state that fresh meat and fresh milk contain the essential preventive factors. A diet containing a quarter of a pound of lean beef or a quart of milk a day will suffice as a preventive in all but very exceptional instances. The milk may be taken either as sweet milk or as buttermilk, the preventive factors occurring in the protein of the milk. The butter fat, which is separated when the cream is removed, is without preventive power.

In eight cases of pellagra the patients were treated by feeding them beef, and improvement followed in every instance. The doctors emphasize that this is almost certainly not the only way in which immunity may be achieved, but they merely state that such a diet as has been described will prevent the disease. It even seems probable in their opinion that a much less amount of meat or milk will suffice, as an instance of which they cite the relative immunity of oriental races to pellagra in spite of a diet in which meat or milk forms a small part. Other foods are apparently equally efficient preventives, they state, but what these foods are is not as yet known.

But enough is now known, according to this report, to prevent the occurrence of the disease, to cure cases of at least moderate severity, and to establish that the primary cause of this serious and frequently fatal ailment is a faulty mixture of protein in the diet, or a deficiency in some dietary complex, possibly a vitamine, rather than a germ infection or excessive consumption of starchy foods.

Medical Education in Cairo.—The Royal School of Medicine at Cairo, formerly known as the Egyptian Government Medical School, and still better as the Kasr-el-Ainy Hospital and School, is an institution with a long and chequeured history, says an editorial writer in the *Lancet,* March 29, 1924. Founded in Napoleonic times, afterwards fostered by Mahomed Ali, it has languished from time to time, to revive under some foreign tutelage, which has been at various times, French, Italian, and British. Under the last two British directors, Dr. H. P. Keatinge and Mr. Owen Richards, it has reached a high state of efficiency and developed into an important centre for medical education, being the only one in Egypt. The school is under the direct control of the Minister of Education, but the Under Secretary of State for Public Health is also concerned in the administration of the hospital. The entry is limited to a hundred new students each year, selected from the successful candidates at the examinations for the secondary education certificates in science. The curriculum for the diploma of the Royal School of Medicine at Cairo has hitherto been approved by the Conjoint Board of the English Royal Colleges, who send a visitor to the examinations, which are conducted in English. The diplomats of the Royal School of Medicine are allowed to proceed direct to the final examinations of the Conjoint Board when they come to this country, a privilege which has been extensively used by Egyptian practitioners.

The school at Cairo is well equipped and is staffed by a number of professors, who until recently have been mostly of British nationality with Egyptian assistant professors and demonstrators, although the chair of parasitology was formerly occupied by a German, Prof. Arthur Looss, who made very distinguished contributions to the literature of his subject. The clinical material at the hospital is almost unrivalled. There is an average daily attendance of nearly a thousand patients in the various outpatient clinics. Unfortunately, the hospital buildings are old and incapable of further extension or adaptation, with the result that the arrangements in the hospital are cramped, unsatisfactory and unworthy of the school. We understand that plans were in preparation for a new and up to date hospital near the school, but for some reason this scheme has not yet been put into execution.

The present flourishing state of the school is without doubt due to the good work done by the English professors in the school and hospital with the loyal cooperation of their Egyptian colleagues, and special attention is given in the curriculum to subjects of importance in Egyptian practice, notably ophthalmology, parasitology, forensic medicine, and public health. A large proportion of the successful students enter the Government service, so their familiarity with these subjects is of national importance.

Warning Against Fake Psychologists.—Charging that many lecturers and socalled schools are exploiting unscientific beliefs and practices under the guise of psychology, the National Committee for Mental Hygiene has issued a warning against fake psychologists. "Much that is today called psychology is misnamed," the committee says. "Perhaps no word is more abused. It should not be confused with phrenology, spiritism, faith healing, selfimprovement by magic, psychic phenomena, and the like. Psychology is the science of human behavior. As often happens in the development of a new science, many people have seized upon the opportunity to gain support for their unscientific beliefs and practices. The exploiters of the present interest in psychology may be roughly grouped as follows:

"First, there are certain lecturers who are going about the country organizing classes or advertising selfimprovement courses in the name of psychology.

"The second group consists of those correspondence courses that make extravagant claims for developing the mind and the will. These courses are alleged to be doing a land office business.

"Then there are special book publishers, who write and issue sets of books and magazines purporting to discuss psychological subjects, which have a wide circulation.

"It is conceivable that some, at least, of the students of such courses are inadequate personalities, who, from physical or other causes, are unable to compete successfully with their fellowmen, and see in these courses, lectures, and literature a cureall for their troubles. In some instances no harm may result. But when a false sense of security postpones needed medical or psychiatric treatment, disaster is sure to follow. For these persons to resort to courses, lectures, and literature would seem about as effective as for them to carry a horsechestnut, a rabbit's foot, or other charm in their pockets."

An Effective Remedy *for* Nervous Sleepless Patients

Neuronidia

Palatable Well-Tolerated Reliable

Allaying Restlessness and Producing Refreshing Sleep

Especially indicated in insomnia from mental strain, neurasthenia and other neuroses; also an excellent sedative in sea-sickness.

Activities of the Rockefeller Foundation.—A review of the activities of The Rockefeller Foundation in 1923, written by its president, Dr. George E. Vincent, has been issued. It summarizes the year's work as follows:

During the year 1923 the International Health Board, the China Medical Board, and the Division of Medical Education of the Rockefeller Foundation

Supplied fellowship funds for 636 individuals in twenty-nine different countries.

Supported through the League of Nations interchange institutes for fifty-four public health officers from twenty-seven nations.

Arranged international visits of one commission and of twenty-four visiting professors.

Furnished emergency relief in the form of medical literature or laboratory equipment and supplies to institutions in fifteen European countries.

Sent scientific material to Japan after the earthquake and invited a group of Japanese medical scientists to use the laboratories of the Peking Union Medical College as guests of the institution.

Continued to contribute to schools or institutes of hygiene at Harvard, London, Prague, Warsaw, and Sao Paulo, Brazil.

Cooperated in nurse training at Yale University and in France, Belgium, Brazil, China, and the Philippines.

Accepted an invitation from Brazil to participate in a comprehensive attack upon yellow fever.

Had a share in demonstrations of malaria control in twelve American States and conducted malaria surveys or studies in the United States, Brazil, Australia, Nicaragua, Porto Rico, Salvador, the Philippine Islands, and Palestine.

Either continued or began antihookworm work in conjunction with twenty governments in various parts of the world.

Contributed to 183 county health organizations in the United States, New Brunswick (Canada), and Brazil.

Continued a study of the medical schools of the world by visits to Belgium, Austria, Czechoslovakia, Germany, Hungary, Poland, Turkey, Hongkong, the Straits Settlements, Siam, Canada, England, Scotland, Wales, the Netherlands, Mexico, and Colombia.

Offered to contribute 280,750 pounds sterling to the development of medical education in certain universities in the British Isles.

Gave $500,000 to the University of Alberta, and pledged $250,000 to the University of Pennsylvania toward buildings for anatomy and physiological chemistry.

Continued to support a modern medical school and teaching hospital in Peking.

Aided two other medical schools and twenty-five hospitals in China.

Assisted premedical education in several institutions in China and agreed to do this also in Bangkok, Siam.

Lent representatives to governments and institutions for various types of counsel and service.

Continued to support a disease reporting service of the Health Section of the League of Nations.

Contributed to mental hygiene projects, demonstrations in dispensary administration, organization of dispensary work in France, and to other undertakings in the fields of public health and medical education.

Alcohol Displaces Gasoline in Sweden.—Competition between American gasoline and Swedish alcohol and the proposal to relax Sweden's liquor control in favor of the latter has become the subject of warm discussion by motorists in Stockholm. It was all started a short time ago when a Swedish built motor car driven by Swedish sulphite alcohol won a thrilling victory over eleven foreign built cars driven by gasoline. Later the same car took on thirty-six foreign competitors, and when the alcohol pushed it along into third place the driver and mechanician were given a patriotic ovation on the spot.

Now comes the question of how to be sober while boosting home industries. It is not hard for Sweden's thirsty citizens to find friends who know enough about chemistry to make a highly pleasing drink out of sulphite alcohol. Hence, the government authorities have kept the liquid under a ban against general use for industrial purposes. But love of country comes first, and if a Swedish car can beat even American cars—well, the Royal Swedish Board of Trade and the Swedish Liquor Control Board have both recommended the repeal of the restriction of sulphite alcohol. It is said that if the manufacturer pours a lot of methylethylketone, or something like that, into the alcohol, it is made unfit for human consumption. That may be the solution of the problem.

Sulphite alcohol is a byproduct of chemical wood pulp, and the factories in Sweden have a capacity of about eight million gallons a year. Last year, however, only about six hundred and fifty thousand gallons were manufactured.

Miscellany.

Deterioration of Procaine Solutions.—M. L. Bonar (*Journal of Laboratory and Clinical Medicine,* March, 1923) found practically no deterioration in the anesthetic properties of procaine solutions standing over a period of several months. He found no increase in toxicity or irritability except in cases of gross contamination. The yellow color change is not an index of a change in anesthetic, irritating or toxic properties, but is apparently due to an oxidative process. The sediment in procaine solutions may be due to the growth of molds, the spores of which may be present in the original preparations, and indicate contamination long before an increase in irritability and toxicity develop. Therefore procaine solutions are stable, and if kept sterile and out of contact with air will remain unchanged indefinitely.

Gentian Violet in the Treatment of Empyema. Robert C. Davis (*American Journal of the Medical Sciences,* November, 1923) thus describes his technic. The chest over the fluid area is anesthetized with 0.5 of one per cent novocaine. The aspiration is done with a fifty c. c. Luer syringe connected to the needle by a piece of rubber tubing two or three inches long fitted with adaptors to fit syringe and needle. This prevents air entering the chest at the time of disconnecting syringe and needle and tends to avoid injury to pleura and lung by movements of the patient or of the instrument. An assistant maintains the position of the needle. The fluid is aspirated until the cavity is almost dry, which is determined by the patient beginning to cough. One precaution observed during the first aspiration is not to take out too much when a large amount of fluid is present. Then one half as much aqueous solution of gentian violet (1-2500) as fluid removed is slowly injected into the cavity. The fluid is first warmed to body temperature. This fluid is allowed to remain until the next aspiration, which should be done in from one to five days, depending upon each individual case. During the second and following aspirations a solution of 1-1000 is used.

Combined Craniotomy and Bismuth Treatment in Cerebral Syphilis and General Paralysis.—H. Dufour (*Bulletin médical,* January 12, 1924) calls attention to the assistance afforded by craniotomy in enhancing the efficacy of drug treatment in syphilitic brain diseases. He reports the case of a man in whom, seven years after syphilic infection, there appeared headache, dizziness, vomiting and later papilledema. These conditions were only temporarily improved by antisyphilitic treatment. A decompression operation being then performed, without incision of the dura, the papilledema showed a very gradual and slight diminution; when bismuth treatment was resumed, however, rapid recovery took place. In another case, the diagnosis was cerebrospinal syphilis with mental disturbance simulating general paralysis, without cerebrospinal hypertension. Antisyphilitic drugs failed. The pupils were unequal, distorted and of the Argyll Robertson type. The patient was tremulous, unsteady, apathetic, with exaggerated reflexes and positive Babinski sign. Simple decompression was performed on the left side and bismuth injections resumed as soon as healing had occurred. Three weeks after the operation the patient was discharged, walking more easily, with the memory improved and the psychic disturbances gone. The patient was enabled to work, and the genital function returned. The anisocoria and pupillary irregularity were reduced and the Babinski sign lost on the left side, reduced on the right. The last examination was made about four months after the operation. A third case was one of typical paresis, requiring constant supervision and practically uninfluenced by antisyphilitic treatment. Decompression was performed on the left side and bismuth injections quickly resumed. After some weeks marked improvement was visible, the patient reading the newspapers, helping the orderlies and serving meals to the patients. Memory and consciousness were improved, tremor diminished, the patient remained quiet and the lymphocytes in the cerebrospinal fluid were reduced from twenty-five per cubic millimetre to nine. The author believes this plan of treatment generally indicated where the preventive treatment of cerebral involvement has been inefficient or the usual treatment of the developed brain disease has failed to check it.

Efficient Treatment for Resistant Cases of Pyelitis.—J. Spencer Davis (*Archives of Pediatrics,* October, 1923) states that the treatment of this infection should begin with the removal of any foci of infection, if practicable, followed by alkali or urotropin and a laxative if needed. Some writers prefer the alkaline treatment alone, while others alternate urotropin and acid sodium phosphate with alkalies. The curative value of vaccines is doubtful and only temporary. The use of foreign proteins, such as typhoid vaccine and various serums, is frequently followed by rather severe reactions. The author has used injections of whole blood unaltered by anticoagulants in cases that were refractory to treatment. The blood is usually obtained from one of the parents and immediately injected into the abdominal wall. The smallest effective quantity of blood was found to be twenty c. c. In the severer types of recurrent infections, this amount was found to be inadequate and larger quantities up to one hundred c. c. had to be given. As many as five injections have been given, but in many cases a single injection was all that was necessary. After the injection no medication is given.

Treatment of Obstruction of the Colon.—Arthur H. Burgess (*British Medical Journal,* September 29, 1923) approaches the discussion of the appropriate treatment of acute obstruction of the colon mainly from the clinical viewpoint and considers the cases as the patients present themselves prior to the operation under three groups: 1. Where we cannot tell whether the obstruction is in the ileum or the colon. 2. Where we can locate the obstruction to the colon, but its situation therein is not known. 3. Where the site of obstruction in the colon can be definitely ascertained. If in any case, the location of the obstruction can be assigned to the colon but is not known definitely and if there is no ground for suspecting a volvulus or internal strangulation, the author believes that cecostomy should be the only immediate procedure.

In recommending an infant food —consider its nutritive value first

Cleanliness, digestibility, and palatability are also of importance, but without nutritive value any food would be useless as a body builder.

FOR the infant, breast milk furnishes all of the requirements mentioned. There is no need to seek further for a better food because no one has as yet been able to prepare a formula which can be considered anything other than a second choice.

As a breast milk substitute there is no better food for the infant than Eagle Brand Milk. For more than four years the largest child-feeding clinic in the history of the world has been maintained in the Near East, and Eagle Brand Milk has met every requirement for a complete milk food for the infants and older children throughout this period.

Reprints of clinical experiments with sweetened condensed milk will be sent upon request.

HACKENSACK, . - - - NEW JERSEY, U. S. A.

Industrial Hygiene in New York.—The development of our modern industrial system from the trade guilds of medieval times, which has been one of the most potent factors in building up the type of civilization which we enjoy at the present day, has been attended unfortunately with an excess of attention paid to attaining economic success, to the detriment of the individual worker's health and general wellbeing. Not until lately has the employer begun to realize that it is not only the humane thing to do, but actually to his economic advantage to provide his employees with hygenic conditions in their work.

The importance of industrial hygiene in a community with so many diversified manufacturing and commercial interests as Greater New York, and especially the Borough of Brooklyn, is selfevident. Brooklyn ranks as the fourth largest manufacturing centre in the country, and contains about 8,000 factories, employing 200,000 workers. In 1915 the city established a Division of Industrial Hygiene to study conditions, to help guard against hazards in industry, whether predisposing to disease or to accidents, and to secure the best possible working conditions from a hygienic viewpoint. The national and state legislatures have been somewhat slow in passing laws for the protection of industrial workers; in fact, the United States permits conditions in some factories which are far below standards required in European cities, although our best equipped factories are probably comparable to those of like grading in Europe. For instance, in this country there is more recklessness in the handling of trade poisons. For example, in the making of storage batteries in the United States in 1914 the rate of poisoning was 17.9 per cent., while in Great Britain it was only two per cent.

The chief health risks in industry at the present time have been classified as follows: Dust, fumes, gases, vapor and acids; harmful bacteria; improper ventilation; improper lighting; extremes of temperature and of humidity; excessive strain leading to fatigue; compressed or rarefied atmosphere; unguarded, poorly taken care of, or carelessly operated machinery; fire hazards. The Division of Industrial Hygiene is making a point of studying and getting data on each of these risks, whether they occur singly in certain establishments, or are found in combination, as is frequently the case. Negligence and carelessness are responsible for many cases of injury, and for this reason a safety first campaign by means of lectures, distribution of circulars, and educational posters is being constantly carried on. Unguarded machinery has, in the past, been one of the most potent sources of danger, but such conditions are rapidly being remedied. To prevent fatigue and strain, the relation of natural rhythm to movements and its psychological effects are being studied, and the workers are being taught how to do their work efficiently with the least expenditure of energy. The industrial workers are also being instructed in first aid measures to enable them to be of assistance in accidents and minor injuries. Industrial managements are being encouraged to establish first aid corps, and to install a first aid and minor surgical dressing room, with a nurse in attendance. The importance of submitting to periodical physical examinations is emphasized, and the fact that no new worker should be accepted until he has been examined by a physician to determine his fitness. Instruction in methods of prevention is given, and employers are urged to reduce risks to the minimum in all possible ways, and to make their factories as clean, healthful, and attractive as possible.

The results to an industry where conditions of labor are hygienic will be: 1, the lessening of the labor turnover; 2, diminution of time lost; 3, increase of contentment and happiness on the part of the employees; 4, augmented wages earned and output attained.

Medical Education Around the World.—During 1923 the Division of Medical Education of the Rockefeller Foundation continued to gather facts about the medical schools, numbering approximately 450, which are to be found in seventy-four countries of the world. Much of the material was secured by post, but a good deal was brought home by representatives who personally visited schools in nineteen countries. The data collected have to do with buildings, equipment, curriculum, staff, annual budget, and other significant points.

The returns so far received reveal a worldwide distribution of certain national influences. Thus British ideas and methods give character in varying degrees to medical schools throughout the Empire, from Canada to the Cape and from Halifax through Hongkong to Bombay. The French or Latin tradition predominates in Southern and Western Europe, in Algeria and Syria, in Central and South America, and in Indo-China. German medicine is found to be fundamental in Central and Northern Europe and in Japan. In addition to these variations due to historical causes, the medical schools of the world display wide differences in resources, personnel, standards, and aims, due to varying racial, economic, governmental, and social conditions.

International cooperation between medical centres the world over is tending to make these differences less pronounced. One aim of the Foundation is to facilitate the contracts and intercommunications by which this international exchange of ideas is accomplished. By aiding schools to send official representatives abroad, by inviting commissions from one country to visit another, and by stimulating an international exchange of professors, it is hoped that gradually fruitful interchanges and progressive adaptations will take place.

Since the foundation began to have a part in medical education it has aided in varying degrees 117 medical schools and thirty-one different countries. The policy has been: 1, to help for the most part only such medical centres as are likely to make significant experiments, demonstrate progressive methods, and set standards which will have a wide influence; 2, to contribute only a part of the funds needed for a given project, with the understanding that the remainder will be provided from other sources; 3, to assume no responsibility for administration or supervision of institutions to which gifts have been made; but simply, 4, to help faculties and trustees to hasten the realization of plans which they have worked out and in which they have genuine faith. Furthermore, 5, no assistance is ever given to a medical school until after a representative of the Division of Medical Education has visited it and conferred personally with its teachers and administrators.

An Effective Remedy *for* Nervous Sleepless Patients

Neuronidia

Palatable Well-Tolerated Reliable

Allaying Restlessness and Producing Refreshing Sleep

Especially indicated in insomnia from mental strain, neurasthenia and other neuroses; also an excellent sedative in sea-sickness.

E AND A

Lupulin-Agar in Intestinal Neurosis

In painful digestion and chronic gastro-intestinal affections Lupulin is a desirable antispasmodic, and its prolonged administration does not produce a habit. When combined with Agar as a vehicle a remedy is obtained that slowly liberates the Lupulin through osmosis, allowing the sedative to cover a large area before being absorbed. Agar is eliminated from the intestinal tract undigested, absorbs a considerable quantity of fluid and increases the bulk of the stool. This property is useful in conditions where the feces are dry and reduced in quantity.

A trial package will be sent postpaid for 60 cents.

The World's Oldest Hospital.—In a recent issue of the New York *Times*, a letter to the editor gives interesting data on what the writer considers can rightly be called the world's oldest hospital. This hospital is situated on the Island of San Bartolomeo, Rome, on the site of a very ancient temple. It is known as the Hospital of the Fate Bene Fratelli (Do Good, My Brethren) and also as the Hospital of San Giovanni di Calabita. According to tradition, in the year 291 B. C., a plague was raging in Rome. The Sibylline Books recommended bringing to Rome from Epidaurus a statue of the god Æsculapius as a remedy for the stricken city. In the Lateran Museum an ancient basrelief represents the journey of this image on a barge on the Tiber. On an island in the river a temple was built to receive the statue, and here for centuries the Romans came to be healed, leaving as tokens of gratitude for cures small replicas in terra cotta of parts of the human body, which are still being unearthed. During the Christian era, the island was dedicated to Saint Bartholomew, and in the course of time the present hospital built on the site of the ancient temple to Æsculapius.

Japanese Children Show High Intelligence.—Japanese immigrant children have as high intelligence as the average American school child, according to data made public by Prof. Robert H. Gault, of Northwestern University, after a series of tests of the Japanese children in the public schools of Denver. The Stanford-Binet test of mental alertness was used, but since the children were handicapped by language, the tests were modified to some extent. The children showed a distribution of intelligence similar to what has been found in native born white children. Eight per cent. of them had much more than average intelligence. Similar and earlier studies have indicated that oftentimes Japanese children as a whole are much superior in intelligence to white children living in the same social environment. These data presented by Professor Gault do not indicate much difference from the intelligence of white children.

Safeguarding the Succession of Scientists in Germany.—The plight of young medical scientists in the Central European countries and the Balkans has recently become so critical that the continuity of workers has been seriously threatened. In Germany especially the danger of a breakdown has aroused the anxiety of the scientific world. German medicine, for example, has contributed so much to the common fund of knowledge and technic that the turning of large numbers of young medical investigators to other pursuits would sooner or later affect medical progress as a whole.

The Rockefeller Foundation, in the interest primarily of modern medicine, therefore asked a committee of German scientists to select promising younger workers who if they had no aid would be compelled to turn to other pursuits, and to appoint them to resident fellowships. These provide small stipends together with sums for laboratory supplies and experimental animals. In 1923 the committee granted one hundred and ninety-four of these fellowships. The trustees have authorized the extension of this plan to other countries in which similar conditions may be found.

Following the Acute Infections

prompt and uncomplicated recovery almost always calls for the systematic use of an efficient restorative tonic—a preparation that will place the least possible burden on the digestive and assimilative functions of the body, but will at the same time supply the support so urgently needed by weakened and exhausted tissues.

The constantly increasing number of medical men that have come to rely on

Gray's Glycerine Tonic Comp.

as a reconstructive tonic, tell beyond all question of its efficiency for the foregoing purposes. Under its use, functional activity is promptly increased, the nutrition is rapidly improved, and the defensive forces of the body are substantially raised.

Gray's Glycerine Tonic Comp. is thus recognized by the busy practitioner as a body-builder to which he can "pin his faith" as a dependable means of promoting convalescence and hastening recovery.

A trial of this reliable tonic will show its exceptional value following the acute infections prevalent at this season of the year.

Valentine's Meat-Juice

In **Diarrhoea, Dysentery** and **Cholera Infantum,** in the **Wasting** and **Febrile Diseases** of **Children,** and in the treatment of **Weak Babies,** the **Ease** of **Assimilation** and **Power** of **Valentine's Meat-Juice** to **Restore** and **Strengthen** has been demonstrated in Hospitals for Children.

VALENTINE'S
PREPARATION
NUTRIO PERMIE
MEAT JUICE.
The result of an original Process of Preparing Meat, and extracting its Juice, by which the elements of nutrition are obtained in a state, ready for immediate absorption.
DIRECTIONS-Dissolve one teaspoonful of the Preparation in two or three tablespoonfuls of cold or warm water. The use of boiling water changes the character of the preparation.

Diseases of Children.

W. T. Watt, M. D., *Director Imperial Medical College, Tientsin, China:* "In cases of Infantile Diarrhœa, which weakens and debilitates a child rapidly, I have found VALENTINE'S MEAT-JUICE a great stimulant and quick restorative of vitality. Three years ago when an epidemic broke out in Tientsin, I ordered my staff to try your MEAT-JUICE, which justified all expectations, having been satisfactory to patients and physicians alike."

Dr. Calatraveno, *Late Physician of the Children's Hospital, Madrid, Spain:* "I have employed VALENTINE'S MEAT-JUICE most successfully in cases of convalescence from infectious diseases, and it is especially beneficial for children suffering from urinary weakness caused by extreme debility, as in every case it acted remarkably in restoring their strength with notable rapidity."

Physicians are invited to send for brochures containing clinical reports

For sale by American and European Chemists and Druggists.

Miscellany.

Memorial Meeting for the Late Dr. Biggs.—On April 29th the New York Academy of Medicine held a memorial meeting in honor of the late Dr. Hermann M. Biggs. The speakers, all of whom had been intimately associated with Dr. Biggs and his work, were: Dr. William H. Welch, director, Johns Hopkins School of Hygiene and Public Health, who presided; Dr. Walter B. James, emeritus professor of medicine, Columbia University; Dr. George D. Stewart, president of the Academy of Medicine; Dr. William H. Park, director, Bureau of Laboratories, New York City Health Department; Dr. Matthias Nicol, Jr., State Commissioner of Health; Mr. Homer Folks, secretary, State Charities Aid Association; Mr. Ira A. Place, vice-president, New York Central Railroad, and Dr. Livingston Farrand, president, Cornell University.

Dr. Welch spoke briefly of the lifework of Dr. Biggs, emphasizing the broad general medical training which he had, and which so well fitted him for his success in later years, both in public health work and private practive. Dr. Park and Dr. Nicoll outlined the progress made under Dr. Biggs by the city and state health departments respectively, and Mr. Folks spoke of his association with private public health organizations. Dr. Farrand, as the last speaker, paid a high tribute to the character of Dr. Biggs, when he said in part: "The disorder of a war torn civilization is characterized by a reign of prejudice and an exhibition of loose thinking and hasty judgment, which is nowhere more noticeable than in this complacent democracy of ours. It is minds and characters like those of Hermann Biggs of which this country stands most in need."

Physical Effects of Starvation.—What long continued famine does to human beings is vividly shown in the form of a coldly scientific article on the effects of the recent famine in Russia recently published as a translation from the work of a Russian scientist, Prof. Alexis Ivanovsky, of the University of Kharkov. Not only loss of weight, but a shrinking of several inches in stature and a general drying up of the whole bodily frame similar to that experienced in advanced old age was experienced by Russians suffering from a three year shortage of wholesome food. When it became evident that a period of famine was approaching in Russia, and that it threatened to be of long duration, Professor Ivanovsky enlisted his colleagues in an investigation of the physical effects of starvation. The observations were made on 2,114 individuals, male and female, in all parts of Russia, and were continued for three years, each individual who survived being measured six successive times at intervals of six months.

The most universal and obvious effect of the famine was loss of weight. Not one individual was found whose weight had not diminished, while in a great number of cases the loss was as much as thirty per cent. of the normal weight. Fat was the first to be sacrificed and by the end of the famine had almost completely disappeared in all the subjects measured. After that was used up, the muscles wasted away, then some of the internal organs, such as the liver or pancreas, were affected, while the essential organs, such as the heart and the central nervous system, were little affected.

Bodily stature declined in nearly all cases, the average loss being from 1.5 to 2.6 inches in men, and from 1.4 to 1.9 inches in women. The loss was greater among young persons, but was made up by them more rapidly when food again became adequate. The shape of the head changed. In the average famine sufferer it became relatively broader, the front and back diameter shrinking more than the transverse. The length of the face decreased less than its breadth, resulting in a typically lean, narrow visage. Similarly the nose became narrower and thinner. "In very emaciated people," Professor Ivanovsky states, "the hair grew more slowly, fell out prematurely, and tended rapidly to become gray. The eyes became like those of old people, the skin lost its elasticity and became wrinkled, the gait became weak and uncertain, the body bent. The sexual instinct became very weak or even disappeared entirely. The number of births decreased enormously, while the number of children born prematurely or stillborn increased, as did those born with various deformities."

Because of the irregular diet of indigestible food, ulcer of the stomach became a common complaint. The body largely lost its power of resistance, simple boils easily became carbuncles, and abscesses of the hands were common as the result of ordinary infections. Finally, Professor Ivanovsky considers the psychological factors of depression and apathy to have been of great influence, even to the extent of causing changes in the body structure.

High Rate of Mortality Among Young Women.—Startlingly heavy mortality among young women from twenty to thirty years of age has been found by Rollo H. Britten, statistician of the United States Public Health Service, in an analysis of recently issued Census Bureau figures. The reason for this peculiar rise in death rates is obscure, Mr. Britten states, and cannot be explained as due to violent causes. There has been an increase, he points out, in deaths from causes connected with childbirth. Tuberculosis, influenza, and pneumonia are also evidently involved in the excess rate among the young women. Other facts brought out in the analysis are that cities show a more rapid decline in mortality than do the rural districts; that persons of mature age show an increase in length of life; and that there has been a continuation of the general improvement in the expectation of life at birth, with colored persons showing greater improvement than the whites.

Sanitation, Not Serums, Conquering Tuberculosis.—Hygienic measures alone, without the use of any serums or vaccines, have been responsible for the great decrease in mortality from tuberculosis during the last thirty-five years, said Dr. Hans Zinsser, of the Harvard Medical School, in a public lecture in Boston on the tuberculosis problem. The death rate from the disease in 100,000 of population had been reduced from 326 in 1888 to 114 in 1920, he said. There was no specific nor serum that was a valid protection from or cure of the disease, the lecturer stated. Many had been tried but none had proved reliable.

Latin as Language of Science.—Latin was urged as the ideal international language for scientists by Prof. Roland G. Kent of the University of Pennsylvania at the recent meeting of the American Philosophical Society. It was so used until about 1800, he said. Latin excelled artificial languages because it was more definite in meaning and more precise in expression, Professor Kent stated, drawing added arguments in its favor from its use by zoologists and botanists in the naming of plants and animals, as well as by the anatomist, the physician, and the druggist. He believed that Latin should be reserved for abstracts and results, articles of permanent value, and books of an epoch making character.

Young Animals Are Insulin Producers.—The insulin producing parts of the animal pancreas, the minute patches known as the islands of Langerhans, are more numerous in childhood than in infancy or adult life, according to a paper presented to the American Association of Anatomists by Dr. Milton D. Overholser, of the University of Missouri. The statement was based upon the examination of the pancreas in many albino rats at different ages corresponding to infancy, childhood, and adult life. He found that the number of islets showed a progressive increase until the eighth week of life, and then a decline to a fairly constant number maintained through adult life. The average number of islets was in inverse proportion to the body weight of the animal.

Cut Flowers Kept Fresh by Aspirin.—Cut flowers may be prevented from fading by giving them an aspirin tablet. Norman D. Keefer, pharmacist at the State Sanitarium at Mont Alto, Pa., states that by this method he has not only preserved flowers several days beyond the time when they would ordinarily fade, but has revived them when wilted. The experiments were conducted with chrysanthemums. Some of them were put into water to which an aspirin tablet had been added; the others were put into plain water. Kept under conditions otherwise the same, the drugged blooms outlasted the others by three days. In another case, flowers which had stood in a hot room over night and were badly wilted, were given fresh water to which an aspirin tablet had been added. They revived in two hours, looking as fresh as they did when picked the day before. The leaves, however, remained wilted. The aspirin acts as an antiseptic, interfering with the enzyme which causes the clogging of the stem at its cut surface.

More Physicians Treating Venereal Diseases.—The number of physicians treating venereal diseases appears to be constantly increasing. According to the records of the Division of Venereal Diseases, 2,853 physicians found at least one case of gonorrhea or syphilis during 1923, an increase of 669 over 1922. The total number of physicians submitting specimens to the laboratory in accordance with the Sanitary Code regulations is in reality much larger than these figures would indicate since 935 physicians submitted specimens in 1922 who did not do so in 1923 and 1,367 sent in the required specimens during 1923 who had not done so in 1922. The total number who submitted specimens during the two year period 1922 and 1923, constitutes approximately fifty per cent. of the registered physicians in the State, exclusive of New York.

Value and Limitations of the Röntgen Ray in the Diagnosis of Pulmonary Affections*

BARNETT P. STIVELMAN, M.D.,
Bedford Hills, N. Y.,

It is perhaps fair to state at the outset that there can be no doubt that the intrinsic value of the röntgen ray far surpasses that of any other laboratory examination; that because it brings the human lungs within the range of that special sense upon which we place greatest dependence, it is a method of inestimable value, and that in many cases it is the only method which holds forth any hope of reaching a correct diagnosis. However, in the study of pulmonary conditions it has suffered and may continue to suffer in reputation because, on the one hand, many who are unfamiliar with the type of evidence furnished by this method have expected too much of it, and on the other hand, many specializing in its use have exaggerated its importance and have made claims which are unwarranted by the results obtained. Moreover, because of the supposed infallibility of this method, it seems that the burden of diagnosis of pulmonary disease has in some medical circles actually been transferred from the shoulders of the clinician to those of the röntgenologist and the x ray has been used virtually to the exclusion of the older methods of examination.

It is, therefore, perhaps not untimely to examine into the value and limitations of the röntgen ray in the diagnosis of some pulmonary affections, and though I may only scratch the surface of this most important subject, I shall endeavor to point out some of the difficulties in the interpretation of chest röntgenograms.

It is now universally accepted that because of their anatomical and physiological relation to the lungs, the tracheobronchial glands and the cluster of glands in the hilum region are the first to be involved when large numbers of tubercle bacilli, regardless of the portal of entry, reach the pulmonary tissues. These glands, reacting to the noxious invader undergo inflammatory, and later permanent structural changes which increase their size and make them less permeable to the röntgen ray, with the result that they cast a larger and denser shadow on the röntgenogram than the normal glands. Clinicians will agree that no known diagnostic method will so surely demontrate the existence of diseased glands as the x ray.

On the other hand, these glands are frequently the despair of the röntgenologist because tuberculosis is not the only etiological factor in the causation of this glandular enlargement. The hilum glands increase in size and density in bronchitis and bronchiectasis, and often attain even a larger dimension during and after the exanthemata and more especially measles, whooping cough and diphtheria. Moreover, such glandular enlargement appears early in the course of pulmonary abscess and persists long after most nonspecific pneumonic lung processes. The röntgen appearance of these glands does not point to any etiological relationship, and it is extremely hazardous to make, as is often done, a diagnosis of tuberculous tracheobronchical adenopathy from the x ray plate alone. Many children are often deprived of an education, separated from their parents, and often banished to distant health resorts, on the strength of the röntgen ray appearance of the hilum region. The x ray in such instances is of quantitative rather than qualitative value, and it is the clinical history and the discovery of associated conditions that will solve the problem, and not the röntgenogram. A history pointing to tuberculous toxemia in association with large tracheobronchial glands would suggest that the patient is in need of treatment. On the other hand, when no such clinical symptoms are complained of, no diagnosis of active disease is justifiable even in the presence of such glandular enlargement, and the patient should be left severely alone. It is pertinent to add that the denser the shadow cast by these glands on the röntgenogram the less the clinical value of their discovery, because such shadows show that scarring, fibrosis and calcification have taken place in these glands, which under the circumstances can be placed in the category of harmless historical landmarks.

*Read before the German Medical Society of New York, May , 1923.

PERIBRONCHIAL INFILTRATION.

It requires no expert in physical diagnosis to discover an advanced tuberculous parenchymatous lung lesion, nor a röntgenological wizard to find a similar condition on carefully taken röntgenograms, but peribronchial tuberculous lesions usually defy detection on physical exploration of the chest. The röntgen ray alone will disclose the peribronchial thickening, and sometimes the beaded pussywillow appearance along the ramification of the bronchial tree. On the other hand, similar shadows are cast by conditions other than tuberculous peribronchial infiltration. Chronic bronchitis associated with emphysema and asthma, and bronchiectasis, anthracosis and silicosis are often accompanied by such x ray finding and there are rare cases of lymphangitis malignancy, the röntgen ray plates of which are indistinguishable from tuberculous peribronchial infiltration. Here, as in the first instance, it is the clinical history of the case, the finding of associated conditions, the history of exposure to the dusty trades, and not the x ray, which will clinch the final diagnosis. A diagnosis of active peribronchial tuberculosis should not be made unless there is clinical evidence of tuberculous toxemia, such as elevation of temperature, acceleration of pulse, loss of weight and strength, cough and other findings, in addition to the röntgen ray findings.

Many patients are sent to sanatoria and hospitals for the tuberculous because of the accidental discovery of peribronchial thickening which frequently denotes nothing abnormal or may be due to conditions which require different modes of treatment entirely.

EARLY TUBERCULOSIS.

The röntgen ray is the most reliable method whereby the true extent of any advanced tuberculous lung lesion can be accurately determined. In this respect it surpasses by far the findings of the keenest clinician. It is different in the case of early tuberculosis. Here the clinical history and physical findings at times point to the existence of a small lesion at either apex when the röntgenogram is frankly negative. It appears, therefore, that in a given case a negative röntgenogram does not necessarily exclude the presence of pulmonary tuberculosis. The physical findings and particularly the history of tuberculous toxemia, etc., should be relied upon in arriving at a positive diagnosis regardless of the negative x ray findings. On the other hand, when the history and physical findings are frankly negative and the x ray shows small discrete tubercles or evidence of slight fibrosis at one or both apices, no alarm need be caused at their discovery because the very presence of these discrete and old lesions indicate that the organism has effectively conquered the invading tubercle bacilli and these shadows represent, as has been aptly stated, "the monuments commemorating the battle won by the fighting forces of the host."

TUBERCULOUS AND NONTUBERCULOUS PULMONARY CAVITATION

Almost pathognomonic of pulmonary tuberculosis is the röntgen ray finding of an area of rarefaction or cavitation anywhere but particularly in the upper lung fields, especially if this area is surrounded by an appreciable wall and is situated in the midst of shadows signifying parenchymatous infiltration. It is almost pathetic to watch the keenest clinician miss fairly extensive cavitations which speak for themselves on the röntgenogram. The failure to elicit these on physical examination is due either to the fact that the communication between the cavity and its draining bronchus is temporarily blocked by a plug of mucus or sputum, or the cavity may be entirely filled with fluid, conditions which preclude the generation of those physical signs by which cavities are recognized. Basal cavities and cavitation in the hilum region and more especially pleural annular shadows, which are in reality a form of interlobar pneumothoraces, are more often missed than elicited on physical exploration of the chest, but almost invariably found on the röntgenogram.

However, a diagnostic pitfall can be avoided when it is remembered that not all areas of rarefaction or cavitation are of tuberculous origin. Such areas of rarefaction near the hilum region or basal fields may be due to extensive bronchiectasis resulting from chronic bronchitis, interstitial pneumonia, and changes secondary to pleural disease. These dilated bronchi are engendered by increase in intrapulmonary tension incident to long continued and distressing cough on the one hand, and traction on the outer wall of the bronchi by the contraction of the fibrous tissue when pulmonary sclerosis is present on the other. Indeed, it has long been known that not all areas of rarefaction are due to ulceration of the pulmonary parenchyma. Areas of rarefaction in the lung tissue may be due to abscess formation and when accompanied by collateral inflammation they are in their early stages indistinguishable from tuberculous cavitation on röntgen ray examination alone. Malignant metastatic nodules, when their circulation is shut off, may ulcerate and discharge their contents into the nearest bronchi and thus exquisitely simulate tuberculous cavitation, while streptothricosis and spirochetal pulmonary gangrene may be accompanied by extensive cavitation, which on röntgen ray examination alone are indistinguishable from tuberculous cavitation. In all such instances a painstaking study of the clinical history, symptomatology, reinforced by repeated physical exploration of the chest and particularly careful examination of the sputum, will lead to a correct diagnosis while reliance on the röntgen ray alone may leave cause for regret.

MILIARY TUBERCULOSIS.

The characteristic widely disseminated snowstorm appearance of röntgen ray shadows in acute miliary tuberculosis of the lungs may be simulated to a marked degree by certain forms of silicosis and anthracosis and particularly by miliary pulmonary malignancy and bronchiolitis. The röntgen ray in such cases cannot be relied upon for an accurate differential diagnosis. It is the clinical history pointing to the primary malignant focus or the occupational hazards the patient may have been exposed to that will clinch the diagnosis. A fatal prognosis has not infrequently been given on x ray findings of miliary pulmonary tuberculosis when in reality there existed a temporary bronchiolitis or a more or less innocuous anthracosis.

ACTIVE AND QUIESCENT PULMONARY TUBERCULOSIS

The discovery of a tuberculous lung lesion is of no greater significance than the determination as to whether or not this lesion is quiescent, or in a state of clinical activity. In the first instance, that is when the lesion is inactive, no treatment whatever may be necessary and the patient, under competent supervision, may be allowed to go about his business as usual. On the other hand, when clinical activity is diagnosticated, judicious treatment is to be instituted at once if recovery or an arrestment of the disease is to be attained. This is perhaps the most important problem in phthisiology. The question now arises, what assistance does the röntgen ray offer in the determination of the clinical activity of any given lesion?

Those who are forever on the lookout for a short cut in the practice of medicine and particularly those who enjoy a limited clinical experience claim to have little difficulty in finding evidence of clinical activity on the röntgenograms, and some go so far as to assure us that they are able to foretell certain pulmonary catastrophes as well as evaluate the degree of tuberculous toxemia from the appearance of the x ray plate. On the other hand, clinicians of widest experience do not feel quite so certain that such information can be gleaned from the röntgenograms, because the reparative and destructive forces which may be and frequently are simultaneously at work in any portion of the lung do not easily lend themselves to differentiation even on the autopsy table and areas of fresh tuberculization may be so situated as to be completely obscured by an old thickened pleura and thus elude the röntgen ray. Moreover, the newest and frequently the most active tuberculous foci are most easily penetrated by the x ray and cast but a faint and insignificant shadow on the plate. The collateral inflammation around the tubercles, which to some is the criterion of activity, is present in many nonspecific intercurrent infections which do not influence the tuberculous process adversely and is often absent in the most typical cases undergoing an exacerbation of tuberculous activity. Inquiry into the patient's complaints especially into symptoms signifying tuberculous toxemia, is the only means of determining the activity of any tuberculous process regardless of the x ray findings.

PULMONARY MALIGNANCY

The diagnosis of pulmonary malignancy has been much simplified as a result of the many recent reported studies. Indeed, the relative increase in the incidence of pulmonary neoplasm is in no small measure due to the fact that we are now on the lookout for, and better able to discover, these conditions antemortem. The röntgen ray is at times of inestimable value in the detection of some of these neoplasms, but it often fails us in the most complicated cases. It is a matter of common knowledge that early metastasis in the lung tissue cannot in the majority of instances be discovered without the aid of the röntgen ray, and not infrequently metastatic nodules of much larger size escape detection on most careful physical explorations of the chest only to be easily elicited röntgenologically. It is different in the case of primary pulmonary malignancy. Here the x ray shadow which is usually dense and homogeneous, especially when situated in the upper lung field, may exquisitely simulate an old fibroid tuberculous process with pleural thickening, pulmonary abscess, and localized or interlobar effusion.

Matters are further complicated when there is a pleural exudate secondary to the lung tumor. The röntgen shadow in this case is indistinguishable from an ordinary effusion or extensive pleural thickening. The age of the patient may not help in the diagnosis because both fibroid phthisis and pulmonary malignancy are found in patients of the same age group. The differential diagnosis will then rest on the clinical history and not the x ray. A history of pulmonary complaint of long standing, especially cough, hemopytsis frequent colds with elevation of temperature, when associated with bilateral disease and evidence of bronchitis and emphysema will speak in favor of pulmonary tuberculosis even though the sputum may give negative findings. A history of a recent pneumonic process or surgical intervention in the upper respiratory tract followed by profuse and foul expectoration, clubbed fingers and evidence of toxemia, will speak in favor of pulmonary abscess. Thoracentesis will help in the determination of the presence of a localized or interlobar effusion. On the other hand, a history of cough of more recent onset, in a patient past middle age, loss of weight, troublesome and persistent pain on the involved side of the chest, and particularly early dyspnea in the absence of cardiorenal disease, is suggestive and requires further investigation. If in addition to such a history, physical exploration of the chest discloses an absolute unilateral lesion with a flat note on percussion, feeble breath sounds or cornage and some evidence of glandular enlargement, especially when tubercle bacilli cannot be found in the sputum, a diagnosis of pulmonary malignancy may safely be made. When there is a coexisting effusion, a diagnosis cannot be arrived at röntgenologically unless some of the exudate is removed and replaced by air in accordance with the method recently described.

ACUTE AND CHRONIC PNEUMONIC PROCESSES

Acute pneumonic processes are easily identified röntgenologically but it is well to bear in mind that even in such instances the evidence is quantitative and not qualitative because the x ray shadow does not point to the etiological nature of the pathological process. Atypical lobar pneumonias are frequently confounded with pneumonic phthisis and unless the clinical course of the disease is carefully studied and other laboratory findings consulted a differential diagnosis may be impossible. The same condition obtains in chronic interstitial pneumonia. Here the röntgen evidence is in itself rarely sufficient to point to a definite diagnosis. Unilateral chronic pleuropulmonary tuberculosis, especially the types which follow pleural effusions and the suspension of pneumothorax treatment, is indistinguishable röntgenologically from interstitial pneumonia of nonspecific origin. In such cases we must resort to the clinical history, and especially, careful sputum studies, for a differential diagnosis. A history of cough, expectoration and recurrent attacks of fever, night

sweats and other evidence of toxemia will point to pleuropulmonary tuberculosis, whereas a history of lobar or repeated bronchopneumonia or empyema treated by aspiration or thoracotomy together with signs and symptoms of bronchiectasis will speak in favor of chronic interstitial or fibroid pneumonia.

PULMONARY SYPHILIS.

In recent years the subject of pulmonary syphilis has been widely discussed. The time has not yet arrived when the frequency of its occurrence can be correctly estimated. Suffice it to say that it is seen less often than some röntgenological reports would indicate. Whether it is encountered in the form of diffuse fibrosis or gumma of the lungs a definite diagnosis cannot be reached on the basis of a röntgenologic examination alone. In the first instance the plate cannot be distinguished from pulmonary sclerosis of nonspecific origin and in the latter case it may exquisitely simulate malignant metastasis, localized pleural effusions, pulmonary abscess and at times patches of frank pulmonary tuberculosis. Here again it is the clinical course of the disease, the results of the physical, sputum and blood examinations that must determine the true nature of the affection.

I have attempted to delineate the value and limitations of the röntgen ray in the diagnosis of the more prevalent pulmonary conditions and hope that I succeeded in pointing out the pitfalls in the interpretation of some röntgenograms. I have omitted the discussion of the various types of pneumothorax, pleural effusions and bronchial affections for obvious reasons. The question as to which method of examination, physical or röntgenological, is supreme, is beside the mark. Both methods are adjuncts of the greatest value to the history, particularly if we are informed of their limitations. To depend upon one method to the exclusion of the other is to invite diagnostic disaster. It is no less the duty of the physician to collect, coordinate and weigh carefully the evidence discernible by all methods before arriving at a final diagnosis as it is the legal obligation of the judge to examine all witnesses before pronouncing a verdict.

Frenzied Therapeutics in Tuberculosis

LEROY S. PETERS, M.D.,
Albuquerque, New Mexico

In our endeavor to find some therapeutic agent that will cure tuberculosis or tend to eliminate certain of its disagreeable symptoms, we have built up an armamentarium that bids fair to bury the patient under an avalanche of drugs and serums.

Let it be understood in the beginning that I am not a therapeutic nihilist, and let it be further understood that I have treated tuberculosis by both methods, the sane and the insane—the drugless and the drugged, and after seventeen years devoted to this special work I am firmly convinced that the tuberculous patient is, in many instances, treated to death.

The days of mysticism in medicine are over. The tendency of the honest members of the profession is to play their hands, face up. We leave secrecy to the quacks and charlatans and allow them to imbue their victims with the depth of their superhuman power. We have nothing up our sleeve, so to speak, that even hints at the cure of tuberculosis, and the physician who lays claim to such ability is either a fool or a careless handler of the truth.

You think perhaps I speak of the men who are granted to be fakers. Not so, for our own ranks are full of men who pose as tuberculosis specialists—many at the head of socalled reputable institutions, who try everything new that drug houses are wont to foist upon an unsuspecting profession, and after filling their patients full of the socalled specifics, and what is worse full of hope for speedy cure, discard the treatment for something still more recent and with still greater claims for efficiency. One need but glance over the digests of the world's literature for any given year to find scores of new remedies advocated which in the succeeding years' reviews will be discarded, to be replaced by something new or different. Is it any wonder when we find facts such as these practised by a supposedly honest profession, that the laity cross their fingers, and slightly wink the other eye at the mention of a quack cure?

Can we expect to have our opinions or our advice taken by the sick when they have so many times before been led along on slippery paths by a regular practitioner who had something just a little bit different and a little more efficacious than his colleague?

I think back a few months ago when my local county society decided to expose the Abrams treatment. This was done to the satisfaction of the county society, the American Medical Association and the National Tuberculosis Association, but not to the satisfaction of the laity. They felt sorry for the men whom the regular profession were prosecuting. It so happened that one of Abrams's disciples was a member of a local business men's club and was up for expulsion on the grounds of fraud. His lawyer made merry with the medical profession as a whole, and before the trial was over one would be almost forced to believe the Abrams practitioner a model of virtue and the medical profession a bunch of highwaymen. One argument that stands out in my memory was this:

"Doctor, you grant that many times the medical profession takes up some new drug or method of treatment and after trying it for a year or two, decides it is of no value and then discards it. Was this not true of tuberculin, mercury succinimide and many other remedies too numerous to mention? Will you grant this to be a fact? Why then should not the gentleman in question use the Abrams treatment until he is convinced of its value or of its worthlessness."

Do you not consider that a good argument, and are not the members of the medical profession to blame for making it possible for any attorney to use such argument with such telling effect? Try to combat it before a lay audience and you are doomed to failure.

When I first entered sanatorium work I felt that to hold patients in an institution it was necessary to offer them something definite—something they could not get outside. I was further imbued with the idea —and I still am—that patients do much better under institutional care than they do in boarding houses or their own homes. With this idea firmly rooted, I felt that anything which tended to keep them in a sanatorium was a justifiable method of treatment, and thus worked to that end. The hypodermic needle and syringe were worked overtime—vaccines and tuberculin were administered, plus iodine and guaiacol—the intestinal hormones, and many other substances. In fact, so imbued was I with the sanatorium care of the tuberculous, that I wrote a long article detailing my results. I think I almost convinced myself. As time went on one by one the various treatments were dropped. I remember how I tried thirty patients on a tuberculin experiment, taking thirty cases as nearly alike as it was possible to choose—giving ten Von Ruck's vaccine for tuberculosis—ten Denys's filtrate and ten nothing. At the end of a year if there was anything in favor of any group, the medal should have gone to the nontreated individuals. That was seven years ago and I have not used tuberculin in pulmonary tuberculosis since.

It is interesting here to briefly review the conclusions reached by F. Neufeld, formerly assistant to the late Robert Koch (1). He asserts that Wright's opsonin hypothesis is deficient as Wright did not substantiate his hypothetical deductions by animal experimentation. The clinical results by this method are no better than by the usual tuberculin treatment.

Animal experiments have shown that old tuberculin exerts no immunization effect whatever. The patient becomes very rapidly habituated to even increasing doses of tuberculin. Koch's expectations from his newer tuberculins have not been realized.

Neufeld considers that the experimental basis of the treatment by Deycke and Much with partial antigens is defective. In his opinion experimental proof is lacking, that Much's preparations are superior to other tuberculins, or that with their aid anything essentially different can be effected.

The use of acid fast cultures and other recent preparations have not satisfied the highest expectations that some entertained. This is true of Friedmann's vaccine.

Neufeld emphasizes the fact that there is no prophylactic vaccination against tuberculosis that is applicable to men. Children inoculated by the Friedmann method may contract the disease and die just as well as those who are not inoculated. He vigorously condemns the proposed immunization of children by injections of attenuated human bacilli or bovine bacilli.

The general findings of Neufeld are that none of the tuberculin preparations have ever displayed any immunizing action. There is as yet no method of vaccination available to man.

So many men are apparently horrified by the low grade secondary anemia in tuberculosis and immediately inject hypodermics of iron in some form or other into the unsuspecting patient. As a matter of fact, the average daily minimum intake to keep the body in iron equilibrium is between six to twelve mg. One finds in the ordinary diet between eleven and nineteen mg.—the average being sixteen mg., which one can see at a glance is more than sufficient to meet the iron demand.

In some work done by Rowe (2) he showed that iron ammonium citrate ten per cent. solution injected in one c.c. doses daily was efficient, but that it produced no better results by hypodermic means than by oral administration, and was much more painful. The old idea of gastric irritation is a relic of the days when they used the tincture of ferric chloride, an irritant preparation. There is no irritation from reduced iron—the ferrous salts or the organic preparations.

But why worry about iron anyway. The anemia of tuberculosis is secondary and when the cause is removed, the anemia corrects itself. Unless the red count is low and the hemoglobin is below eighty per cent., there is no occasion to administer iron in any form. The anemia will take care of itself in a very short time.

Besides there is another side to the iron question. Many investigators maintain that the administration of drugs has no effect on anemia. Whipple and Robscheit (3) produced secondary anemia in dogs by bleeding and then carried out a very exhaustive study as to the influence of various iron preparations in the regeneration of blood. These investigators state that their experiments give no support to the time honored custom of administering iron and certain other drugs in conditions of simple anemia and that the burden of proof rests with those who claim that any given drug is potent under such conditions. They attributed the improvement to dietetic conditions rather than to drugs. Musser (4) confirmed the work of Whipple and Robscheit.

Owing to the statement that tuberculosis is accompanied by a deficiency of lime salts, calcium has been frequently advocated. As early as 1783, Tourcroy suggested its use and some one has been suggesting it ever since. Moendl (5) reports on the intravenous use of calcium chloride for severe hemorrhage. He gives five c.c. of a ten per cent. solution every eight hours until the bleeding stops and continues it once a day for several days thereafter. I have given calcium chloride intravenously for hemorrhages, and after two weeks find the patient still bleeding. It's the old story over again—there is no cure for hemorrhage. The fact that we have a thousand and one remedies for bleeding speaks more loudly than words for their uselessness.

Just what calcium does in hemorrhage is open to question. The normal contents of calcium in the blood is more than is required for coagulation and further increase of calcium does not increase coagulability. Hess showed that the addition of calcium to hemophilic blood in vitro delays rather than hastens its coagulation, and it has not been shown that there is a deficiency of calcium in conditions such as hemorrhage, aneurysm, hemophilia, purpura, and other conditions.

Bastedo asserts that the use of calcium by mouth for hemorrhage is questionable, but states that the results of different experimenters in the effect of blood coagulability of calcium is conflicting. Many observers believe that the continued use of the drug increases the coagulation time.

As to its use in the treatment of tuberculosis *per se,* there is also a wide difference of opinion. For many years there has existed a tradition that those who work with lime are immune to tuberculosis, or if they have the disease, they become cured. Tweddell (6) states that manufacturers of lime and gypsum informed him that their employees were apparently immune to tuberculosis, claiming that the fine particles of lime and gypsum are carried by inhalation into the lungs. The lime coming into contact with the moist tissue of the lungs forms calcium hydroxide, which acts as a caustic and antiseptic and is then absorbed. Gypsum acts in the same way. He also cites observations and references to show that calcium added to the food not only helps prevent tuberculosis, but also favors the healing of wounds and fractures. Just as competent observers, on the other hand, (Kahn, 1914, and Mohler and Bergein, 1917, quoted by Sollman, 7) have shown that no such characteristic changes occur and extensive studies in calcium metabolism in tuberculosis fail to show that it exerts any favorable influence on the disease.

The copper treatment of tuberculosis was heralded a few years ago as a wonderful therapeutic aid. Many American clinicians immediately took up the method before any attempt had been made to verify the claims of the first clinical reports. The result was failure and disappointment again, both to physician and patient. Later, investigators have given their reports and their conclusions after exhaustive study, are not flattering to copper as a therapeutic agent in tuberculosis.

The same can be said for the vital dyes. Great assertions for these dyes were made by the Germans but American investigators, notably De Witt, are in total disagreement.

It is unfortunate but nevertheless true that many research workers rush into print with half completed experiments and make claims for this and that method which are wholly unwarranted from the evidence at hand. I recall a meeting of one of the national medical societies where I listened an entire morning to papers on the experimental side of medicine, and when the program was concluded I felt as though I had been running around in a circle. Thinking perhaps my brain had failed to grasp the deep principles established by such exhaustive work, I asked one of the best known men in the medical profession what he had gleaned after the morning's symposium. His reply was quite to the point: "It seems to me," said this gentleman, "that these physicians are attempting to justify their salaries to the directors of the institutions with which they are connected."

The success Chaulmoogra oil achieved in the treatment of leprosy naturally turned the thoughts of investigators to its use in tuberculosis, and a literature is already growing that bids fair to rival reports of other socalled cures of the past. So far the same criticism holds good—too few patients, too short a duration of treatment, and too hasty conclusions by men who are anxious to report results from the use of new and untried drugs.

When will the profession learn that end results are what is sought in any given treatment of tuberculosis, and not the temporary improvement of symptoms that go with the psychology of a new cure.

Others are now trying to aid in the treatment of tuberculosis by the introduction of tablets supplying at one swallow all the vitamines that the body may need for years to come. In fact if one listens to the ready tongue of the salesman or to the literature sent with the preparation, one is convinced that the use of garden vegetables is no longer a necessary adjunct to the average diet, and to place a few bottles of the tablets among your tuberculous patients will aid materially in effecting a speedy cure.

Let us review briefly the few really valuable adjuncts in the treatment of tuberculosis other than rest and graduated exercise, good food, fresh air, the oft discussed but never settled question of climate, and last but not least, proper supervision.

Above all, excepting those mentioned, I would place artificial pneumothorax. Regardless of opinions to the contrary this treatment has come to stay. Most of us who have used this method over a number of years and who have followed the patients carefully after discharge, are not as optimistic over the end results as we were in the beginning of the work. However, even considering the palliative results in many cases, the percentage of arrests are sufficiently great to feel that its use is indicated always in the proper type case, and that because of these palliative results, its use should not be restricted.

Next in order of usefulness I would place heliotherapy if one restricts its use to socalled surgical tuberculosis. There are a few who advocate its use in the pulmonary form of the disease, but their reports as to end results are not definite and must be taken with the proverbial grain of salt. Personally, I have never been able to convince myself that it has the least value in the pulmonary form.

Surgery of the chest has recently come into its own after many years of experimental work, and it seems necessary now to grant a place to thoracoplasty. When one finds it impossible to produce an artificial pneumothorax because of adhesions, and the opposite lung is free of activity, with the patient's general condition fairly good, this operation is justifiable.

The work in this country by men like Archibald of Montreal, has certainly added much to the safety of the operation and has placed it on a firm foundation as a valuable adjunct in the treatment of tuberculosis.

Many methods of immobilizing the affected side have been advocated after an unsuccessful attempt at artificial pneumothorax, but that which offers the best chance for real effectiveness, is a socalled pneumatic lung splint. This consists of a jacket made to measure, into one side of which is inserted a pneumatic bag which is inflated by a valve and stem leading to the outside. One can exert any pressure that the patient will permit and I know from observation that it will immobilize a chest. I have been trying to get the splint perfected ever since I had it called

to my attention, but as yet have been unable to get one that would hold air. Apparently this is due to a poor grade of rubber, but so far the manufacturers have been unable to remedy it. I know from my limited use of this splint that it offers a better method of immobilization than anything so far offered in lieu of artificial pneumothorax.

This, I believe, covers the field of useful adjuncts. There are many others advocated, but they are either useless or in the experimental stage and call for no comment.

By briefly referring to what I consider legitimate methods of treatment, I hope I have convinced my audience that I am not a therapeutic nihilist and further, I trust that I have made clear the utter uselessness of the vast storehouse of drugs and serums that are given to the unsuspecting patient with the hope of curing a chronic disease, that at best we expect in the majority of cases only to arrest the pathology and restore a physical condition somewhere nearly to par, with the added assurance of reasonable health for years to come. To offer more than this with our present knowledge of tuberculosis, is to create false hopes that sooner or later must be sadly broken.

I wish to express my thanks to Dr. E. A. Duncan, of El Paso, for some of the reviews on iron and calcium metabolism.

Accessory Sinusitis—Sources of Diagnostic Error

MAURICE M. POMERANZ, M.D.,
New York

Accessory sinus disease, so common an entity, so prosaic in its apparent simplicity, and a condition so easily diagnosed, does not present so simple a picture to the radiographer.

I have examined within recent years approximately three hundred cases of accessory sinus disease and during this time have been often impressed with the divergent opinions voiced by medical men concerning the value of radiographic examinations as a routine measure in all cases where such procedures would seem to be indicated. My purpose is to clarify some of the obscure points in diagnosis and to analyze some of the common sources of error.

Radiographic examination of the sinuses in the hands of a skilled radiographer is an invaluable aid in the interpretation of a diseased condition and I feel that greater cooperation between the practitioner and the röntgenologist, would prove of great value in the logical and successful treatment of a case. One is so prone to criticize the radiographic interpretation, that a finer appreciation of some of the technical difficulties encountered in the laboratory, might perhaps explain a good deal. I hope to call the attention of the reader to some of the common sources of error in the usual cases examined. The anatomy and technical demonstration of the sinuses will not be entered into, in any great detail, but sufficiently to consider intelligently the points under discussion.

Strange as it may appear to the initiated, I have time and again been requested to ray the accessory sinuses of patients who had already been under treatment by means of suction, or other methods, and been requested to furnish detailed information as to the condition of these sinuses. To expect to demonstrate anything but granulations seems absurd, but the error has been committed time and again.

NECESSITY OF PRELIMINARY EXAMINATION

A thorough physical examination is as important in this as in any other type of disease. It is astonishing sometimes to note the number of extrasinus conditions that simulate true sinus disease. Causes of indefinite facial pain, neuralgias and headaches should be thoroughly analyzed before the attention of the examiner is focused on the accessory sinuses, as a possible source of pathology. Errors of refraction, as well as symptoms of focal infection, warrant investigation. Infected teeth, gum abscesses and unerupted teeth, often from the mere superficial examination, present what appears to be typical sinus pictures. "It is my opinion that the majority of cases of chronic disease of the antrum arise from some necrosis of the jaw and teeth." (1) Intranasal conditions such as deviated septa, enlarged turbinates, etc., which, while they often are the cause of sinus disease, will present a typical sinus picture when no such pathology is present.

RADIOGRAPHY VS. TRANSILLUMINATION

The value of radiographic diagnosis has often been the subject of unjust animadversions as compared with the office routine of transillumination. Pontoppidian gives positive illumination in 144 out of 152 cases, and believes röntgenology to be superfluous (2). We do not believe that this is a universal average, nor do we believe that the consensus of opinion of otolaryngologists would support that view. "Even with the best transillumination outfits in the majority of cases a radiograph will have to be taken in order to determine whether a diseased antral condition is present or not (1)."

References to the anatomy of various skulls indicate, we believe, the dangers of relying solely on this method as a diagnostic means.

A true appreciation of the normal as well as variations within the normal, is absolutely imperative in the consideration of any pathology. The frontal sinuses are often absent, and when present vary in size, shape and depth, as well as in the thickness of the anterior bony wall. The practical importance of this is great. In transilluminating frontal sinuses, particularly, we are treading on dangerous ground. An area which does not illuminate properly will

often be classed as a pathological sinus, whereas there might be an anatomical absence of one. I do not contend that transillumination is utterly valueless but I do believe that too much reliance is placed on this as a diagnostic means. It is of certain value in the antra, but we believe it absolutely worthless as a definite guide in frontal sinus disease. On the other hand, the radiographic error in interpretation is often due to an imperfect appreciation of the various shades of density, which the various pathological sinuses will produce. Let us consider several types of cells as an illustration of this point.

1. The small thick walled sinus of average depth may well give the appearance of the presence of either pus or granulations, whereas no such pathology may be present, or conversely.

2. The large deep thin walled sinus may give a normal appearance and yet contain granulations or pus.

The reasons for this will be apparent. The small sinus will often, but not invariably, have a thick anterior wall with little air containing space, the ray will have greater difficulty in penetrating and the result is a radiograph that might be variously interpreted. In the second case cited, the easy penetration of a large thin walled air containing cavity will often obliterate finer shadows indicative of pathology.

3. In early cases of acute sinusitis, particularly in the small type sinus, the exudate present very often will not add materially to the density of the cells under examination, and with the present limitations of the x ray will not cast an appreciable shadow in the sinus area. This diagnostic error holds for both the x ray and transillumination (3). It is just this finer appreciation of shades and shadows that materially reduces the percentage of error. Röntgenologists will often have a sort of intuitive knowledge of the amount of density to expect from the various types of cells.

4. The fourth source of röntgenological misinterpretation is fortunately rare. We refer to the mistaking of an absent sinus for one that contains granulations or pus. It should be stated in this connection that no matter how much pus there be contained in a frontal sinus, there should remain a limiting cellular border; its absence means the lack of a frontal sinus and can usually be checked on the lateral view of the skull. This fact is invariable, according to the experience of the writer.

ETHMOIDAL SINUSES

In rereading many of the films referred for confirmatory diagnosis we have noted a tendency to ignore in the written reports the presence of ethmoidal cells in the frontal region. These cells are commonly infected and when present give symptoms identical with those of true sinus disease. The failure to note such a condition results in unwarrantable delay and annoyance to the physician and to the patient.

The handicaps usually met with in accessory sinus disease do not as a rule pertain to the ethmoidal sinuses. Here the easy accessibility of the field under scrutiny permits of quick and easy diagnosis. It is to be remembered, however, that those of us living in large cities have always some degree of ethmoidal infection and a word of caution may not be amiss in considering the operability of a given condition. It is to be deplored that there is not a more universal use of the x ray in considering indefinite causes of eye disease. The information that may be obtained in these cases is often of great importance.

SPHENOIDAL SINUSES

The sphenoidal sinuses are more commonly involved than is suspected. Here again technical difficulties complicate the diagnosis. The usual view employed is a lateral view of the skull, which superimposes most of the bony structures of the face over the region of the sinuses and furthermore, gives but at best, a lateral view of the area under investigation, making accurate interpretation difficult. We have adopted the Pfahler technic of demonstrating these cells and have found that it considerably facilitates the diagnosis of sphenoid disease. Briefly this method consists of a two by three film placed in the mouth between intensifying screens. The exposure is then made through the vertex of the skull. The advantage of this method is that it gives a horizontal projection of the ethmoidal cells and a very distinct picture of whatever pathology exists. (4). This method also affords a means of comparing both the right and left sphenoidal sinuses—so difficult to obtain on other views.

MAXILLARY ANTRA

I appreciate the disappointment of the otolaryngologist in failing to obtain pus on puncturing a röntgenologically positive antrum. Possibly a brief exposition of the sources of error may explain the why and wherefore. A common source of error is due to the position in which the exposure is made. The usual position is a posteroanterior view with the tube so placed as to project the petrous portion of the temporal bone into the lower half of the orbit, out of the maxillary area. This as a rule permits of easy and reliable interpretation. However, this is sometimes incorrectly or imperfectly done with the result that a bone shadow of considerable density is thrown over the maxillary area. The writer has in addition to the usual posteroanterior view added the Walters-Waldron position. In this position exposure is made through the vertex of the skull, with the chin of the patient placed on the plate. (5). Radiographs taken in this position are of invaluable aid in checking up any pathology demonstrated by the orthodox posteroanterior view. This is also a view that will check any demonstrated frontal sinus pathology. In this method, the petrous portion of the temporal bone is projected out of the field under examination. Ofttimes, a definite diagnosis may be made by this position where the pathology on the posteroanterior plate was obscure. We have had such striking results with this technic that we heartily recommend it as a routine measure in all cases.

Röntgenologically, it is impossible to differentiate between the presence of either pus or granulations in the antra. Various media have been injected in an attempt to see whether a radiographic difference could be detected but no working formula has as yet been devised. (6). Hence on the radiographic report it is usually stated that pus or granulations may be present and consequently if on puncture no

pus is obtained, the fault is not with the radiographer, since the antra might still contain granulations or a markedly thickened membrane. We have never yet seen a fluid level in the antra; the technic of the exposure calls for the patient to be placed face down; consequently the fluid, if present, will move up and homogeneously overshadow the antra. This is noted in lung work, where the chest will be homogeneously clouded if the patient is placed flat on his chest and the exposure is made. In the upright position, a typical fluid level may be demonstrated in the presence of air in the pleural sac.

It is perfectly possible to conceive a condition where a trochar and cannula introduced into a pus containing antrum may still fail to demonstrate pus since the level of the floor of the antrum is more often below the level of the floor of the nasal cavity. Here the level of the fluid may be below the level of the exploring instrument and no fluid be obtained as a result. Often the viscosity of the fluid is such that it is too thick to flow readily through the needle. Repeated irrigations will often demonstrate pathology not found at the first examination.

CONCLUSION

I have attempted to enumerate briefly the common sources of error in accessory sinus interpretation. The importance of a general clinical and laboratory survey of the case has been emphasized. I believe that the x ray examination should be considered an important correlating source of laboratory aid and, while not infallible will, as a rule, give a correct lead on a case. It is not my contention that transillumination is worthless, but conclusions based on its employment are hazardous and for the protection of the patient as well as the physician, its findings had best be corroborated by the x ray. In any case of accessory sinus disease, the clinical symptoms must a priori be considered and the operative course must be guided solely by its indications.

Chronic Bronchitis of Nasal Origin*

W. F. VON ZELINSKI, M.D.,
U. S. Army, Fort Bragg, N. C.

Chronic bronchitis of nasal origin seems not to have attained to the dignity of being mentioned in our textbooks, at least I cannot recall having noticed it in any one of a half dozen works on general medicine including one published a few months before this article was prepared. As far as I can determine, nothing of much importance along these lines appeared in the literature previous to about 1916, at which time the intensive study of chronic coughs among the soldiers of the warring nations drew the attention of observers to the nasal origin of many bronchial diseases supposedly having a tuberculous foundation. My own interest in this subject dates back from the latter part of the year 1919. This article is based on the assumption that a bronchitis persisting for longer than fifty days may be classified as chronic. It may be stated in passing that at present I do not consider any patient with a cough or bronchial disease as having been thoroughly examined which does not include an examination of the nasopharynx and nasal accessory sinuses. How this is to be done need not be detailed here, as methods of procedure may be found in the various special and many general texts on diagnostic technic; suffice it to say that the difficulties are not insurmountable to an average well trained physician.

The history, symptoms and treatment may be considered along broad lines as it is not considered necessary to go into minute details as this would only be repeating what is already well known.

In general, the history of the class of cases we are considering, shows that in the beginning the syndrome observed in acute coryza with tracheobronchitis is also present here, but with this difference, the onset is not so acute, nor the reaction so marked, symptoms apparently persist for a longer time, vary in intensity from what we might regard as repeated acute flareups to a stage where there is a constant slight annoyance. It is to be noted that at no time from the beginning of the condition do the symptoms ever entirely disappear, rather do they tend to become more and more persistent until a chronic stage is reached wherein the symptoms are well marked and quite definite. Among the symptoms we find always a persistent cough, usually but not invariably accompanied by more or less obstruction to nasal breathing, at times amounting to complete obstruction and manifest mouth breathing; this latter is termed the bronchitis of the corked nose.

Close inquiry will disclose that these patients virtually blow their nose into the pharynx which not only infects the lymphatics of the pharynx but produces a descending infection of the larynx and trachea. What follows is usually the condition for which the patient seeks relief, namely, a laryngitis or bronchitis or both with persistent cough.

*Read before the District Medical Society of North Carolina at Southern Pines, November, 1922.

The most frequent sources of infection in my experience have been: Chronic purulent ethmoiditis, adenoids, maxillary sinusitis, chronic purulent sinusitis, and pansinusitis, in the order named. Cases traceable to frontal sinusitis I have not encountered. Three types of cases have been described and will be noted because in a general way they coincide with my observations although few of my cases have been as true to type as here described. The mechanism of the infection is the same in all, there is probably a difference in the organisms involved. I have never worked out this feature, but I am inclined to believe that these are the same as those which cause the original infection in the nose and sinuses.

TYPES OF CASES

A. The infection appears to spread equally through the main branches of the bronchi and to the alveoli. This form may lead to dilatation of the bronchioles, and on auscultation the physical signs of emphysema are manifest. There is no pain, the cough varies, being affected by the atmospheric humidity. When this is relatively high the cough is increased, conversely when the humidity is low and the weather warm, such patients may have surcease from their cough and nasal discharge when this is manifest. The winter months are the worst for these patients for the reasons stated. Among the fairly constant symptoms in these cases is, that the cough is increased on lying down, hence a habit of going to sleep well propped up with pillows. Another striking symptom not only in this but the other types as well, is the hawking, coughing and sometimes profuse expectoration on arising. In this way the nasopharynx is cleared of accumulated secretions which as a rule are thick and tenacious. The secretion from the lungs varies from a relatively thin serous to a thick purulent material. The amount is not constant and changes from day to day.

A rise in temperature is not frequent. I have treated cases in which the temperature ranged from 99° to 101° over a period of two weeks, seemingly being influenced by atmospheric conditions and local treatments to the nose. This is the type of case which has most frequently come to my attention, the most usual coexisting nasal condition being unilateral and bilateral ethmoiditis. Back of this has been a history of influenza or repeated attacks of acute cold. In children adenoids have been the most frequent causal factor.

B. Tracheal or phlegmonous type. Here the pathology in the lung seems limited to the trachea. It is characterized by severe painful paroxysms not unlike asthma, followed by moderate expectoration. With the coughing there is substernal pain. The patients in the few cases of this type which I have observed and treated have never had a rise in temperature. Some have been troubled with moderate dyspnea. The most usual associated disease has been some abnormality in the nasal structures, such as deviation of the nasal septum causing obstruction with hypertrophy of one or more turbinates, generally on the side opposite to the convexity of the septum. There was a history of bronchial symptoms coming on gradually over a considerable period with no remissions.

C. Localized form. In this form the lung involvment occurs in patches in the lobes of the lungs. At times only a small spot, frequently near the apex. This condition is difficult to differentiate from pulmonary tuberculosis, and although all tests and examinations for the latter prove negative there is always room for some doubt. The basis on which one may decide against tuberculosis is the clearing up of the physical signs after a short period of local and general treatment. One such case led me to believe that I was dealing with a fetid bronchitis, until diagnostic puncture of the maxillary sinus brought forth a quantity of foul smelling pus. Subsequent treatment by a dental surgeon cleared up all symptoms. Incidentally the few cases of this type which I have treated have shown maxillary sinus infection.

TREATMENT

It goes without saying that from what has already been stated, every abnormal condition of the nasopharynx and sinuses should receive proper attention and treatment. I have nothing new to offer along these lines, the procedures are mostly surgical and have been tested by time and found successful when performed by competent men.

You are perhaps interested in the general measure which may be adaptable in these cases, and while what I have to say along these lines may not be novel, yet I venture to hope that some of you will find something of value in my suggestions. Though I have had only a limited experience with vaccines, I believe them to be of distinct value as an auxiliary to the local and general measures. Apropos, Mackey (2) in 130 cases found germs in the sputum which seemed of sufficient importance to be incorporated in a vaccine. In about half of the cases the infection was a mixed one. On the whole, these vaccines were so successful that Mackey was forced to the conclusion that the cause of bronchitis, and also some types of asthma, is to be traced to an infected state of some part of the nasal passages. My personal experience has been limited to the autogenous variety. Of drugs, potassium iodide in average dose has been the proverbial sheet anchor. Its influence is most pronounced in ameliorating the lung symptoms, but it seems also to have a beneficial effect on any existing perverted nasal secretion, rendering it more fluid, thus facilitating its discharge and free drainage. Together with the measures directed to the removal of causal factors, potassium iodide hastens and facilitates recovery. I know it is a distinct aid in restoring normal conditions.

Inhalations of benzoin, eucalyptol, menthol, creosote, turpentine and other volatile aromatics generally in combination of two or more of these in vapor form, are of some value, though in my judgment only slightly so. The symptomatic control of the cough is perhaps of the most importance to the patient, and I may add often to the attending physician as well. How futile this proves to be, is well attested by the innumerable preparations put out for this purpose. It must first of all be determined whether or not the cough is productive. If not, codeine in three to six centigram doses is the drug of choice. Sometimes one of the bromides in one to two gram doses will prove effective. These drugs should be used sparingly and for no greater period than necessary to accomplish their purpose. Many

patients can be taught to control their cough by the exercise of will power, using the drug only as required to prevent loss of sleep. A productive cough should not be suppressed under any circumstances, assuming it will not produce untoward symptoms in other respects, rather it should be encouraged as an aid to the expulsion of accumulated secretions. As an aid I have found nothing better than potassium iodide and ipecac in some one of its fluid forms and in the highest doses the patient's age and condition will tolerate. Ammonium chloride appears to enjoy a considerable reputation as an expectorant, but in my hands its value has proved doubtful under any circumstance. It probably has a slightly solvent action on mucous or mucopus with which it comes in contact, but as this contact is limited to the throat at the moment it is swallowed, its use must be quite limited. In cases where there are attacks or paroxysms simulating asthma, I have used lobelia or belladonna in connection with potassium iodide, or bromide or both, the dose here as elsewhere being varied according to circumstances.

Other measures which have appealed to me as being of benefit in restoring normal conditions and building up resistance have been cold sponging of the chest upon arising for the day to stimulate and deepen the respirations; the breathing and body bending exercises as described in the various drill manuals as used in our army; sports such as will take the patient out in the open in proper weather, such sports to be of a nature suitable to the age and general physical condition of the patient. Climatic treatment when required will readily suggest itself, and is outside the scope of this paper.

In conclusion, the care of a goodly number of cases of the nature herein described, over a period of three years, convinces me that my observations are rational and of practical value. Training in the speciality of otolaryngology together with enough general work due to the exigencies of military service, have enabled me to treat cases from both the specialist's and internist's viewpoint.

Abscesses of the Nasal Septum, Their Etiology and Treatment with Reference to Resulting Deformities*

WILLIAM WESLEY CARTER, A.M., M.D., F.A.C.S.,
New York

I have never seen a case of abscess of the septum that did not result from traumatism, and I believe that this etiology may be accepted in practically all cases. Gummatous, tuberculous and other possible specific infiltrations do not come under our present consideration, we are interested here in those acute abscesses due to the introduction of pyogenic organisms between the layers of the mucoperichondrium of the septum.

It is unnecessary to urge the importance of this subject, for the condition is common and the deformity of the nose and the interference with its function, which almost invariably follows the healing of the abscess, are most disastrous. A blow upon the nose without fracture may result in abscess. The question as to the hematogenous origin of the infection might arise here, but the probability is that the infection gained access to the septal tissues through a rupture of the mucoperichondrium. When fracture occurs there is no question as to its mode of introduction, for all fractures of the nose may be regarded as compound into the nasal cavities.

Abscess of the septum is often slow and insidious in its development; frequently a week will intervene before infection is suspected and the case when seen by the surgeon may present a well developed septal abscess, the mucoperichondrium being dissected up by the burrowing pus over a considerable portion of the septum with much destruction of bone and cartilage support. General turgescence of the nasal mucous membrane may mask the septal condition and make an early diagnosis difficult. Fluctuation in well developed abscess may be elicited by placing the tip of the little finger in one nostril and palpating with a cottontipped applicator on the other side. This sign is of no value in the early stages when the diagnosis is in doubt and when it is most important that the true condition shall be known. A sign which may be considered almost pathognomonic of septal abscess is an abrupt thickening of the septum just behind the columellæ, the septum posterior to this being swollen and inflamed. This point corresponds to the anterior border of the triangular cartilage and is the point of election for making the incision for drainage of the abscess. Emphasis is made of the importance of this sign, for by observing it the diagnosis may often be made before the formation of pus, and when this is done and the proper treatment immediately instituted, the disastrous results to the contour of the nose which invariably follow a well developed septal abscess, may almost surely be avoided.

An early diagnosis is important, too, to insure the safety of the patient, for the infection may gain access to the meninges through the cribriform plate; I recall at least two deaths in my hospital practice that resulted from septal infection being transmitted to the brain in this manner.

Hematoma of the septum may be differentiated

*Read before New York Medical Union, March 27, 1923.

from abscess by the history of rapid development of the swelling after injury. Following the submucous operation an impending abscess of the septum may be suspected at once if there are symptoms of an acute coryza accompanied by the usual general symptoms of infection, such as chilly sensations, rise in temperature, and malaise. Hematoma following this operation is extremely likely to develop into abscess. Personally I regard hematoma as an early stage of abscess and treat it as such. Experience teaches us that we are fully justified in assuming that the clot is infected.

TREATMENT

Treatment should be begun at the earliest possible moment and should be vigorously prosecuted. I have found the following procedure satisfactory and have abandoned other methods in favor of it: An L shaped incision is made on the left side, the long arm of the L corresponding to the anterior border of the septum and the short arm being extended backwards along the floor of the nose. The incision is made freely into the abscess cavity. I then wash out all of the pus with warm, sterilized salt solution and swab out the entire cavity with sterilized absorbent cotton until it is practically dry. Two applicators are wound with cotton; one is dipped in pure carbolic acid and the other in ninety-five per cent. grain alcohol. The abscess cavity is then swabbed out with carbolic and this is immediately followed by a thorough swabbing with the alcohol. I then introduce one of my gold wire splints into each nasal fossa. This is a distinct advantage over the old method of packing the nose with gauze, for not only are the septal walls kept in contact with each other or with the septal cartilage and bone, but the nasal cavities are kept open for respiration, for cleansing and for drainage. The nasal cavities should be sprayed frequently with glycothymolin and the bowels should be kept freely opened by saline catharsis.

I have controlled some very severe infections by this method of treatment and I have seldom had to repeat the carbolic application. If the case is one of hematoma whether it is due to accidental or operative trauma, the treatment is the same.

The prognosis in abscess of the septum varies according to the length of time that has elapsed since the infection began. The longer this has lasted the more likely is the upper edge of the septum to be dislodged from its position between the lateral cartilages, where it serves the important function of the keystone of the nasal arch, also the more apt is there to be complete destruction of the bony and cartilaginous septum. If the vitality of the septal bone and cartilage is destroyed, no effort should be made to remove the dead tissue, unless it is free in the abscess cavity, for the effort to remove partially destroyed tissue may result in further injury to the framework of the nasal arch.

If the upper edge of the septum, the keystone of the nasal arch, is dislodged or destroyed, the remaining segments will establish the arch on a lower plane, giving rise to the familiar saddleback deformity. The deformity becomes apparent as soon as the abscess has healed and the swelling in the nose has disappeared. Later the distortion of the nose becomes much more marked, due to the cicatricial contraction of the scar tissue in the walls of the old abscess cavity. The deformity is still further accentuated by the skin and tissues over the cheeks which accommodate themselves to the changed shape of the nose, and finally the whole face appears broad, flat and heavy. For some reason not quite plain to me, but probably due to interference with drainage from the sinuses, atrophic rhinitis very frequently develops in these cases shortly after the deformity becomes established.

There is at the present time only one method known for the satisfactory and permanent correction of this type of deformity, and that is by the transplantation of autogenous bone and cartilage grafts. This method of correcting these deformities was developed by me about fifteen years ago, and some of my oldest cases attest the value and permanency of the results.

While the essential principles involving the use of these tissues in correcting this deformity have remained the same, I have made some changes in the technic which have added greatly to its efficiency. The details of this operation have been published elsewhere, suffice it to say that a strip of conjoined bone and cartilage from the rib of the patient is introduced through a slit in the roof of the left nasal cavity in such a manner as to build up and support the nasal bridge. The upper end of the graft is contacted with the frontal bone just above the nasal spine; it establishes bony union at this point in about two months. The lower end of the graft is composed of cartilage and extends into the tip. It has sufficient firmness to support the tip and yet it does not interfere with its resiliency.

Depressed deformities treated by this method remain permanently corrected. The bone and cartilage, when properly transplanted, are not absorbed, as is shown by numerous serial x ray plates of some of my oldest cases.

These depressed deformities of the nose following septal abscess should be corrected by the transplantation of bone and cartilage as soon as the abscess has healed and the infection has been completely eradicated.

Since the absence or impairment of the vitality of the septum and consequently loss of its developmental force, is certain to result in a flattening of the nose later in life, if the injury occurs during childhood, the interesting question arises as to what if anything can be done to prevent the development of this deformity; in other words, is there any substitute for the developmental force of the septum? Of one thing we are absolutely certain and that is that the autogenous bone transplant, properly introduced and in such a manner that it establishes bony union with the frontal bone, is the only hope upon which we may rely. Here cartilage will not do, for this tissue remains indefinitely the exact size, shape and consistency as when introduced.

A close radiographic study of a large number of cases in which bone had been transplanted from two to twelve years, it is distinctly disclosed that the growth of the bone is influenced by the demand that is made upon it. In those instances where the depressed deformity had been great and especially where much scar tissue had been present, the strain upon the transplant, in its effort to maintain the

elevated and normal contour of the nasal bridge, had been very great and it had increased greatly in size at those points where the strain was greatest.

While this phenomenon does not prove that a piece of rib grafted into the nose of a child whose septum as a developmental structure has been destroyed, yet it does show that a bone graft is a living, growing tissue and that with reasonable certainty we may rely upon it to assist in developing the nose, which if let alone would certainly be flat. I have transplanted bone in several instances where the patient's nose had not assumed its adult proportions. These cases are scattered all over the country and I have been unable to follow them up personally, but the corrections were satisfactory at the time and so far as I know the subsequent development of the nose has kept normal pace with its facial environment, certainly I have heard nothing to the contrary. One of these patients I saw five years after the operation; there was no deformity and the nasal development was normal. I am not sure, however, that the developmental power of the septum in this case had been destroyed by the abscess.

In conclusion, I wish to emphasize the importance and desirability of doing this corrective work intranasally; chiefly because infection is less likely to occur, and there remains no disfiguring scar. Long ago I abandoned my original external operation chiefly for these reasons. The external operation, which is easier and diagrammatically very attractive, appeals to the novice in this work who has not yet developed that sense of touch and delicacy of rhinological technic which is required in doing the intranasal operation. It is unnecessary even to refer to the undesirability of obvious scars in this most important cosmetic field; these necessarily follow external operations.

2 West Sixty-ninth Street.

The Waring Suction Tonsillectomy

J. B. H. WARING, M.D.,
Blanchester, Ohio.

To enucleate or not to enucleate; that is the question. But when it is answered in the affirmative, I think another question can be asked. Is it possible for us to perform tonsillectomy in a better, cleaner, easier, more rapid manner than the ordinary technics in use today will permit? This question may be answered in the affirmative also.

Development and widespread acceptance by the profession today of the focal infection theory, have invited a more intensive study of the tonsil, both in health and in disease. No longer is the tonsil exclusively in the domain of the nose and throat specialist. Tonsillectomy is being performed with increasing frequency, not only by the throat specialist and the general surgeon, but also by the general practitioner. In the hands of the trained throat specialist almost any tonsillectomy technic gives excellent results, but for the beginner, the occasional operator, and even the general surgeon, many of these tonsillectomy technics are difficult to acquire, and often times in such hands the end result leaves a good deal to be desired.

The great number of tonsil enucleation technics, and the still greater number of tonsil instruments on the market today, show the need for a simple, safe, clean, rapid and bloodless tonsillectomy.

Tonsillectomy technics in use today may roughly be classified as some form of snare and dissection; or some modification of the ingenious Sluder technic. It is unnecessary to dwell upon the difficulties and dissatisfactions of present day tonsil enucleation methods; they are known to every operator of any experience.

To eliminate the trials and tribulations of the average tonsillectomy, I wish to present a new method of operation—namely, suction tonsillectomy. The principle of suction, applied through a tonsil suction tube of special design, is employed to draw the tonsil out of its bed between the pillars of the throat, and hold it in a semiinverted position in the mouth of the suction tube, until a dull wire snare loop previously threaded over the suction tube, is carried over the base of the tonsil and tightened down until it is enucleated by a virtual shelling out process, cleanly, rapidly and in a practically bloodless manner.

Nearly every well equipped general practitioner of today has in his office some form of compressed air and suction pump; certainly every physician doing tonsil work has such a pump apparatus as well as a tonsil snare. This is practically all the armamentarium required for suction tonsillectomy; only enough suction to grasp the tonsil firmly and hold it snugly in mouth of suction tube is required—from fifteen to twenty-five inches of vacuum—and every modern suction pump will deliver this degree of suction. Likewise any type of tonsil snare may be employed; ratchet type snares, such as the Pierce-Mueller or Eves, afford a more gradual enucleation where desired; but this is not an essential.

Suction tonsillectomy is a one man job, applicable equally well to office or hospital. This is of importance to the small town physician, who often has a considerable number of cases where tonsillectomy is urgently indicated; but who heretofore has been sadly handicapped, if not prevented from doing his own tonsil work, by lack of hospital facilities, assistant and nurses. I do not advocate tonsillectomy as a minor office procedure, to be performed recklessly by every physician, whatever his training and experience. It should be treated as more of a major operation and best performed in hospital or well equipped clinic. Inasmuch as tonsil enucleation is performed by the beginner as well as by the occasional operator in general practice, however, it is a step forward if we can give them a technic which is simple, safe, rapid

and capable of uniformly good results in such hands —a technic which will enable even the expert to do his tonsil work in a better, more rapid manner.

This suction tonsillectomy will do. It renders unnecessary the elaborate instrumental outlay usually seen at operation; and is applicable equally well to both local and general anesthesia. In fact, its superiority is marked over the ordinary methods.

Where local anesthesia is employed, the tonsillar field may be anesthetized by whatever technic the operator is accustomed to; owing to its rapidity, patients do not have time to become frightened; in fact the entire technic is so simple it may be demonstrated to them in advance, and their possible fears dissipated. Likewise a formidable array of tonsil instruments is not spread before the eyes of the patient; and the absence of bleeding, with its resultant hemostatic efforts, is decidedly reassuring to the patient. Where indicated, tonsillectomy may be performed by the suction method under local anesthesia in the comparatively aged, with surgical shock practically absent.

Under general anesthesia an assistant to administer the anesthetic is the only assistance required; owing to its rapidity of action, anesthesia need be only comparatively light and brief. No time under anesthesia is lost in hemostatic efforts. The operation is particularly valuable in large clinics, where the time and energy of the operator must be conserved to the utmost; patients can be operated upon rapidly and cleanly as fast as nurses or assistants can prepare them under local or general anesthesia. Where general anesthesia is employed, the field of operation may be kept clear of mucus and saliva by the same suction tube as used in operation, a small vacuum bottle of about one half pint capacity being incorporated in the rubber tubing suction circuit between suction tube and pump proper, to serve as a reservoir.

No preliminary dissection is required. High visibility is one of the strongest features of suction tonsillectomy; every step in operation is under direct inspection of the operator; the clear glass of suction tube and the clean, bloodless field enables the operator to see exactly what he is doing all the time. There is no blind groping, or hasty efforts to complete dissection and enucleation in a blood filled pharynx. No injury to the pillars, uvula or throat muscles follows the suction shelling out tonsillectomy. Consequently the fossæ are left clean, throat structures uninjured, and complaint of postoperative sore throat reduced to a minimum. The majority of these patients eat their regular meals the day following operation.

Suction tonsillectomy should almost, if not completely, eliminate the all too frequent pulmonary abscess after tonsillectomy; if, as seems the consensus of opinion today, this complication is due to or resultant from aspiration into the air passages of gross infective masses of tonsillar exudate or pus. With the first application of the suction cup to tonsils, they are vacuum cleaned of sometimes astonishing amounts of pus or foul smelling exudate, often completely concealed and unsuspected deep in the tonsillar crypts. This is so completely removed from the tonsils and from the operative field as a whole, that it is my firm belief that this vacuum cleaner suction cleansing of the tonsils should be used as a preliminary step in technic in every tonsil enucleation.

To eliminate the only technical difficulty encountered in development of suction tonsillectomy and render the technic not only simplicity itself, but one hundred per cent. perfect on all types and sizes of tonsils, a tonsil suction tube of special design was perfected, which I have named the Waring tonsil suction tube. These tubes of clear glass, with a rubber tubular handle for ease of manipulation, have a straight shaft of about eight inches in length, terminating in a bulbous head set at about right angles to shaft, with a smooth sloping shoulder falling in sharply to a full oval aperture perpendicular in its longest diameter. The suction tube is connected to suction pump by a flexible rubber tubing of about four feet length and about one quarter inch diameter, fairly stiff in body so as not to collapse when suction is on; the end of rubber tubing is simply slipped on and off shaft of suction tube to make or to break suction. There is nothing complicated, nothing to get out of order. The tubes are easy to clean and to sterilize. With a little practice the operator quickly selects a tube of sufficient mouth size to include the given tonsil to be enucleated.

Fig. 1—The Waring suction tonsillectomy. The right tonsil is engaged in mouth of suction tube, connected by flexible rubber tubing A to suction pump. Snare loop has been carried down over base of tonsil in readiness to enucleate.

THE OPERATION.

The technic is the same under local and under general anesthesia. A Waring tonsil suction tube of size suitable for the given case is selected from the set, and connected up to suction pump by the flexible rubber tubing above described. The loop of a tonsil snare wire is now threaded over the bulbous head of suction tube, and allowed to hang freely suspended from shaft of suction tube, out of the way until required. A fairly heavy snare wire, about a No. 8, is best, as the dull wire pinches rather than cuts its way through the tissues joining tonsil to throat structures proper, thus giving more hemostatic effect. Any type of tonsil snare may be employed. Under direct inspection the bulbous mouth of suction tube is now carried into mouth, and its aperture placed between the pillars and over the tonsil to be enucleated; the clear glass and clean field enables the operator to see exactly the situation at every stage. Suction is now turned on, when it will be seen that the tonsil is drawn completely out of its bed and held in mouth of suction tube in a semiinverted position. If for any reason, suction grasp of tonsil may be instantly released by sliding off rubber tubing from suction tube shaft, and just as easily regrasped by suction. There is no laceration of tonsil, or pulling out effect, as so often happens with the best of tonsil forceps, tonsil screws, etc. As the tonsil is drawn out of its bed by suction, the pillars are rather pushed aside, or let back out of the way of injury.

Next the tonsil snare is taken up in the unoccupied hand; for the right tonsil the suction tube is applied and steadied with the right hand, and the snare held in the left. For the left tonsil, the left hand holds the suction tube and the right hand the snare. There is no difficult instrumental manipulation to acquire. Nothing to unlearn. Success of the operation does not depend on strong arm muscular exertion. There is no type of tonsil the operator cannot get easily and cleanly by suction tonsillectomy. This cannot be said of many of the older operations.

On the right tonsil, with the suction tube steadied in the right hand, the snare loop is now carried down over bulbous head of suction tube on to base of tonsil to be enucleated; this step is rendered practically automatic by the smooth, sharply insloping shoulders of the Waring suction tube; the snare loop is now tightened down over base of tonsil and the tonsil enucleated rapidly; or if desired for greater temostatic effect, slowly enucleated as is possible with ratchet type tonsil snares such as the Pierce-Mueller, Eves, and others.

It will be found the tonsil is practically shelled out cleanly with its capsule in a completely inverted position, the dull wire of snare loop completing the inversion produced by the suction tube. Where the ordinary snare is employed, the right hand holds the suction tube throughout, but where a ratchet type snare is employed, the suction tube is released as soon as the snare loop is tightly engaged around base of tonsil, and both hands then employed to steady and complete enucleation with the snare. It will be found the fossæ are left clean, other throat structures uninjured, and the operation practically bloodless in every case; except, of course, patients of hemophiliac tendencies, which should be determined in advance if possible by blood coagulation time tests.

The left tonsil is enucleated in same manner as the right, with exception as stated, that the left hand is employed to hold snare, while right hand steadies suction tube.

SUMMARY

Briefly summarized, the advantages of suction tonsillectomy over the old methods are as follows:

It is so simple that even the beginner and occasional operator can do good, clean, rapid, practically bloodless tonsil work from the start.

Its rapidity is remarkable; this makes it easier for both the operator and the patient.

It is essentially a one man job, and does not require the train of assistants, and extensive instrumental armamentarium usually met with in tonsil work.

High visibility is a strong feature; the field of operation is under direct inspection at every stage; and there is none of the awkward and difficult intraoral manipulation often required in the various Sluder technics.

It is equally applicable to local and to general anesthesia operations; and there is no type of tonsil, the operator cannot get easily and cleanly. Its superiority is quickly demonstrated on the small, deeply submerged and badly adherent tonsils, so difficult of satisfactory attack by the ordinary operative methods.

Because of its clean type, lack of bleeding and injury to contiguous throat structures, a minimum of postoperative sore throat is complained of; and convalescence only about half as long as after the ordinary tonsillectomy technics.

Postoperative lung abscess is practically unknown after suction tonsillectomy—no cases being reported anywhere to date; and in general the end results after suction tonsillectomy will be found more uniformly satisfactory both to operator and to patient.

Endobronchial Treatment of Bronchopulmonary Affections

J. PAUL DE RIVER, M.D.,
San Francisco, Calif.,
Consultant in Bronchoscopy and Plastic Surgery of the Face of the U. S. Marine Hospital, San Francisco, Calif.; and Chief of the Eye, Ear, Nose and Throat Section District No. 12, U. S. Veterans' Bureau.

Endobronchial therapy is rapidly taking its place in the field of modern medicine. The use of the bronchoscope is no longer limited to foreign body removal, but as an adjunct in the treatment of infections of the lower respiratory tract it stands out preeminently.

It is logical that the best way in which to combat disease is to get directly at the part involved and attempt to stamp out the infection or prevent further activity. It is in an attempt to accomplish these ends, when dealing with tracheobronchial infections, that the use of the bronchoscope is essential because there is no other means in the treatment of the affections of the lower respiratory tract that an exact local application can be obtained. Bronochoscopy has enabled us to observe accurately the pathological changes resulting from diseased conditions of the lower respiratory tract and lungs, and to cope with these changes by therapeutic applications of various medicinal substances directly to the involved areas.

The types of cases in which endobronchial therapy is applicable are many. It has proved its efficiency in the treatment of lung abscess, bronchiectasis and bronchial asthma. However, in my opinion, there is still a fertile field as yet undeveloped where endobronchial therapy may be used with gratifying results. In this field comes the treatment of chronic bronchitis and pulmonary tuberculosis. By the use of intratracheal injections combined with direct applications under the guidance of the bronchoscope, we have the therapeutic triad with which to combat the invading armies of infection. We have the most effectual weapons of defense and attack of the present day.

F. Guyot (1), experimenting on animals, has

proved that after intratracheal injections the liquid penetrates the lung from top to bottom in six hours, the epithelial cells multiplying, many showing the presence of the oil that had been injected. He further claims to have cured encysted pleurisy with two months' treatment.

Hamant and Julien (2) have successfully treated tuberculosis of the larynx and lungs by intratracheal injections.

Ginsez (3) has obtained gratifying results in the treatment of gangrene of the lung by intrabronchial injections. From the foregoing we note how valuable is intratracheal and bronchial therapy and by the combined use of direct applications or intratracheal injections under the guidance of the bronchoscope, we are able, in many cases, to stamp out infection.

The use of the bronchoscope is akin to the cystoscope, which is so successfully used in the treatment of bladder and kidney infections, and in many cases the results are equally gratifying.

The technic required is of importance. Local anesthesia, using a solution of ten per cent. cocaine, applied directly to the epiglottis, vocal cords, and passing a swab well down into the trachea, will facilitate the passage of the instrument and will render the patient in a condition whereby the applications or injections may be readily made. Through the loss of sensibility of the mucosa the cough is suppressed, enabling the patient to retain the medication for a long period. The size of the instrument used is of importance. The smallest instrument possible is of advantage. In adults I prefer Jackson's seven millimetre bronchoscope.

Having carried out these preliminaries, the bronchoscope may be passed with ease, and direct applications or injections made without further trouble. A variety of drugs have been used. However, in the application of any substance, one should be governed by the pathological findings encountered upon direct examination. If the mucosa is inflamed, a ten per cent. solution of argyrol or a weak solution of silver nitrate is preferred. For the anemic conditions, so frequently observed in tuberculosis and chronic bronchitis, silver nitrate in various strengths up to ten per cent., and glycerine tannate ten per cent., have been found to yield results.

The bronchoscopic picture encountered in the examination of cases of chronic bronchitis and tuberculosis often reveals changes in the mucous membrane of the trachea and bronchi. The mucosa is, as a rule, of a grayish color, frequently showing areas of fibrosis. The lumen of the smaller bronchi is at times completely occluded, as the result of edema. There is often a profuse secretion, viscid in character, and at times purulent. This is retained, due to the loss of muscular tone. It is by the stimulation of the mucosa, causing a shrinkage of the lumen and stimulating the activity of the flaccid muscles that we assist nature to expel the retained secretions and allow the lung to be properly aerated.

I have used the bronchoscope with good results in many cases of tracheobronchitis, following the inhalations of the various gases that were used in the world war, and in these cases, the appearance of the mucous membrane presents a different picture to what we find in the bronchitis following influenza and pneumonia, or accompanying pulmonary tuberculosis. In these gas bronchitis cases the mucous membrane is highly injected. It is of a beefy red appearance. In this type of case solutions of argyrol and liquid petrolatum, biweekly applications or injections, yield good results. My colleagues have frequently asked if I do not fear traumatism and discomfort experienced by the patient in the passage of the bronchoscope. The traumatism should be nil if the operator is familiar with the technic of bronchoscopy. The slight amount of discomfort experienced by the patient is largely overcome by the use of local anesthesia, and lastly, the amount of discomfort experienced by the patient in no way compares to that experienced by the passage of the cystoscope, which is universally used by the genitourinary specialist in the treatment of bladder and kidney infections.

Before attempting a bronchoscopic treatment it is of utmost importance that the psychological element of the patient be considered. He should be brought face to face with his true condition, explaining just what is expected of him and the results that are to be obtained. Once gaining his cooperation the operator is enabled to carry out the treatment successfully. When his confidence and cooperation are gained the technic becomes very simple.

The first time the instrument is passed, many will complain of a little discomfort; the second time, a little less, and after the third they will often come to you and ask you to pass the bronchoscope because they have experienced such marked relief following its use.

Although the bronchoscope has been used in the control of tracheal and bronchial hemorrhage, it is the author's opinion that it should not be used in the ordinary cases of tuberculosis where hemoptysis or pulmonary hemorrhage is present. This is certainly a contraindication to the use of the bronchoscope, and its injudicious use in these cases may yield disastrous results.

CONCLUSION

The bronchoscope may be used with gratifying results, not only for the removal of foreign bodies from the air passages, but in the treatment of diseases of the lower respiratory tract and lungs, including pulmonary tuberculosis and chronic bronchitis. By its use we are able to accurately make direct applications or injections, and in many instances head off infection.

By stimulation of the flaccid musculature we help nature to throw off the secretions, and thus allow the lung to perform its physiological functions.

The traumatism and discomfort are very slight and should not stand in the way of its use when indicated. Thorough understanding of the relief to be gained and the cooperation on the part of the patient are the two essentials.

The Treatment of Gastroenteroptosis and the Futility of Surgical Intervention*

CHARLES D. AARON, M.D.,
Detroit, Michigan,
Professor of Gastroenterology and Dietetics in the Detroit College of Medicine and Surgery

I propose to discuss the treatment of gastroenteroptosis and the futility of surgical intervention. Far be it from me to belittle the achievements of modern surgery. It is a great art, and it has attained to power in the realm of lifesaving such as has perhaps been reached by no other department of medical activity. It is decisive in practice, beneficent in results, and, allied with asepsis, the greatest boon that has come to mankind. As its technic becomes more certain, its service for good will become incalculable. But because it is so fascinating and so wonderful in effect, the surgeon is frequently misled into urging surgical intervention and the patient into blindly trusting it. It is the internist to whom the patient, weak from his operation, comes in search of final relief. It is the internist who appreciates the fact that many an apparently successful operation entails serious disabilities which diminish the patient's efficiency, and, in many cases, jeopardize his health to such an extent that he never can resume his place as a man of service to his community. And often it is the internist's conviction that conservative methods, slow but sure, would have served more reliably than operative intervention.

The fact is that many surgeons are too quick to appeal to the scalpel; in other words, they are too ready to follow up a hasty diagnosis with a hasty operation. A röntgen ray examination with the bismuth mixture may show a displaced stomach, a prolapsed transverse colon, or ptosis of the hepatic or splenic flexure; but such conditions do not imply that surgery is necessary. So long as gastrointestinal motility is not interfered with, there is no absolute indication for surgical intervention. A stomach can be displaced anywhere from its normal position down to the symphysis pubis without interfering with motility. The fluoroscope shows that such a displaced stomach can properly empty itself into the duodenum. There is no disturbance of motility even when parts of the intestine are dislocated. When the röntgenogram shows that a gastroenteroptosis exists, a hasty operation does more harm than good. The surgeon may believe himself driven to resort to operation lest a delay should prove fatal; but a premature intervention may be as calamitous as a tardy one. What busy surgeon follows up these cases and knows just what becomes of them, other than that they left him after the successful operation? What does he know as to the disabilities the patient has had to accept as the price of his recovery, disabilities which may have reduced his earning capacity and forced him to change the whole trend of his life? There are insidious dangers which follow in the wake of speculative operations. Without doubt many operations are a testimony to the enthusiasm of operators; but enthusiasm is not without its dangers. We hear a great deal about the success of operative intervention; but to be perfectly fair the failures also should be recognized.

One of the operations to which gastroenteroptotic patients are frequently and unnecessarily subjected is gastroenterostomy. To be sure, a gastroenterostomy, when indicated, brings results of the most wonderful kind, especially in cases of obstruction of the pylorus. But no operation has been more abused and thus become the cause of more harm. Its use can never be justified as a cure for simple gastroenteroptosis with accompanying neurosis. We also find surgeons anchoring a displaced kidney, attaching the colon to the abdominal wall, suspending the stomach in a hammock made of the great omentum, plicating the gastrohepatic and gastrophrenic ligaments, overlapping the recti muscles, suturing the gastrocolic omentum to the anterior abdominal wall, and resorting to other socalled original expedients for the cure of gastroenteroptosis. The unreasonableness of these operations is clear when we recall that in over ninety per cent. of cases of gastroenteroptosis the position of the abdominal viscera is in normal conformation to the physical status of the body. Patients suffering from such a characteristic bodily form do not respond to surgical intervention. The

*Read before the twenty-fourth annual meeting of the American Therapeutic Society at San Francisco, June 22 and 23, 1923.

condition is one of general relaxation, which is not helped by a local operation or the fixing of any part of the abdominal viscera. These patients become neurasthenics and suffer from nervous dyspepsia associated with gastric and intestinal atony. Even if we suture the kidney, stomach, or colon, we do not in the slightest degree improve the neurosis. The anatomical dislocation of the organs is of minor importance in contrast with the pathological condition of the nerves involved in the digestive system. It is to be hoped that with a better understanding of the pathological anatomy of gastroenteroptosis the *furor operativus* will be broken and yield to internal medicine.

By mere inspection of a case we are able to base upon our observations a reasonable suspicion of gastroenteroptosis. The elongated, narrow, flat thorax, long neck, prominent scapulæ, depressed epigastrium, and protuberance of the hypogastrium upon standing are quite characteristic. In making a diagnosis of gastroenteroptosis, the finding of a nephroptosis assists quite materially. A palpable kidney is pathognomonic of gastroenteroptosis (1). We know that a dropped kidney is usually an incident to general ptosis, and that symptoms referable to the kidney are mainly due to intestinal displacement. The starting point of a dropped right kidney is a sagging in the flexure of the ascending colon. This is followed by a ptosis of the transverse colon, which brings about traction on the pylorus, and this in turn causes a displacement of the stomach. Ptosis of the hepatic flexure of the colon causes a tugging on the peritoneum, inducing a downward and inward displacement of the right kidney. For this reason a palpable right kidney is an indication of a dislocation of the stomach or of part of the intestine. A movable kidney is not a pathological condition, for every normal kidney, on account of its relation to the diaphragm, moves during respiration. It is pathological only when it is palpable. Why induce a pathological condition by surgically fixing a kidney that is physiologically movable? (2). It is not enough that the patient survives the operation; he should, if possible, emerge from it unharmed. Many patients are permanently disabled by adhesions and other complications following such an operative procedure. The rest in bed after surgery allows the abdominal viscera to fall back to their normal position. This relaxes the mesenteries and ligaments, relieving the tugging on the nerves. The temporary improvement makes it appear that the case is proceeding to recovery. But further observation of the case often shows that this is a mere illusion; some substantial agency of relief is required. This, I believe, in common with many surgeons and physicians, can be brought about by a properly fitted bandage. Surgeons, in fact, often advise the use of a bandage after the operation, during the patient's convalescence, but they credit the operation rather than the bandage with the improvement that ensues.

The conservative method of treatment of gastroenteroptosis is coming into favor because of its evident and many sided merits. It comprises dietetic, physical and medicinal treatment, combined with the accurate fitting of an abdominal bandage. Of the former I need not speak at great length, for it is well known. But as to the bandage I may say that I devised a form of its construction in 1897 (3), and have employed it ever since with almost uniform success in a variety of cases. I have thus far personally fitted 2,722 patients. All of these bandages are made by the same manufacturer.

Before deciding upon the necessity of a bandage, I have found Glénard's "belt sign" (*l' preuve de la sangle*) of great value. Standing behind and passing his arms on either side of the patient, the physician places both his hands on the lower abdominal wall and raises the entire abdominal mass above the pubes. Then, abruptly removing his hands, he allows the abdominal mass to fall. Should the patient feel distress or discomfort by this release of the temporary support, the indication is clear that an abdominal bandage is needed. If, however, the patient feels no relief when the abdomen is thus lifted, the bandage will have no good results. My bandage raises the intestine by pressure upon the hypogastrium from below upward. This pressure relieves the tension of the ligaments and mesenteries of the abdominal organs. If properly adjusted, the bandage not only affords support to the abdomen, but also allows free and easy respiration by relieving the dragging on the diaphragm. It enables the viscera to function normally, rehabilitating the organism. As soon as the abdominal organs have regained their normal function, the body begins to respond to therapeutic treatment (4).

It is well known that the veins are more easily compressed than the arteries. In gastroenteroptosis the arteries continue to carry the same quantity of blood as before to the organs, but the veins, under more or less external pressure, are unable to carry the blood back. As a result we have a chronic passive congestion, leading to the usual neurasthenic symptoms found in this condition.

The bandage rapidly corrects this interference with the circulation. In the treatment of over 2,700 cases of gastroenteroptosis, each patient having been directly fitted with my bandage, I have been led to believe that 95 per cent. of patients suffering from this condition can be relieved without operative measures. Contrary to the report of former clinicians, the röntgen ray with the bismuth mixture shows that the stomach and intestine can be raised and eventually retained in place by the use of a properly fitted bandage.

The wearing of readymade abdominal bandages which aim to support the abdominal viscera usually ends in failure. The bandagemaker, to whom the order for the bandage is sent, is usually left without any definite instructions as to the results desired. He does not care whether the stomach is below the umbilicus or the colon is in the pelvis; a bandage is demanded of him and a bandage is furnished. At the end of a few days the patient refuses to wear the apparatus on account of discomfort, or severe pain may develop from pressure at some weak point. To attain a satisfactory result each patient should be fitted by the attending physician with a bandage adjusted to his specific condition, with instructions as to its proper application. The wearing of such a bandage not only raises the position of the abdominal organs, but relieves the strain and tugging on the nerves in the mesenteries. In this way the normal function of the organs is reestablished. In other

words, we restore the physiology of the abdominal viscera to normal and obtain, in cases of gastroenteroptosis, a bodily condition which readily responds to dietetic, physical and medicinal treatment.

My Latest Conclusions Concerning Gastric Ulcer*

ROBERT T. MORRIS, M.D., F.A.C.S.,
New York

If Rosenow can pick up a guineapig and give it a pyloric ulcer by inoculating the animal with streptococcus viridans, the "mystery history" of gastric ulcer would seem to disappear. We are left, then, with the simple duty of analyzing the various features of the subject according to methods of ordinary philosophy.

Terminal arteries, elective affinity for toxins, sensitization. These appear to be the three most salient features of the gastric ulcer question. Embryologists divide the alimentary tract into the foregut and the hindgut. For the sake of convenience they sometimes arbitrarily make a third division called the midgut. This includes stomach, duodenum and jejunum.

For our purposes in this paper we are to note the anatomical peculiarity of richness of the midgut in terminal arteries. Arteries of this sort are particularly abundant in the region of the pylorus and duodenum where ulcers are also most abundant. Association of idea must remain closely in touch with association of this latter fact.

Rosenow has shown us that certain areas of the alimentary tract have an elective affinity for toxins of many sorts. These areas appear to have elective affinity for antigens of widely different kinds and the presence of antigens in excess in a given area calls out a corresponding increase of antibodies.

Authors have sometimes called attention to the fact that patients with ulcer of the midgut area appear to have an idiosyncrasy. Idiosyncrasy is only common parlance for sensitization, the latter word being used in its pathological meaning rather than in a physiological meaning which relates to organic processes in general.

In recent years we have become familiar with this subject of sensitization, but more should have been said by gastroenterologists on the subject in its special relation to ulcers of the midgut area. Patients presenting these ulcers appear to have a sensitized endoderm which corresponds to an ectoderm with its demonstrations of urticaria or of chronic eczema. Acute gastric ulcer then is to be placed in the category with urticaria; chronic ulcer with a patch of chronic eczema of the leg, for purposes of comparison. The restricted area of ulcer demonstration relates to terminal arteries. There are no terminal arteries to restrict the area of skin outbreaks.

In addition to our three salient points in connection with midgut ulcer we may perhaps place a fourth feature relating to endocrine dysfunction and wrong hormone production. My reason for making note of this fourth point is that so many of our patients with midgut ulcer present stigmata of arrested development. For example, we shall often find the high arched palate, narrow costal angle, gunstock scapula, coccygeal dimple, relaxed peritoneal supports and other stigmata of racial decline in midgut ulcer patients.

Let us now go back to our first point, the anatomical one, relating to terminal arteries. Twenty years ago I presented photomicrographs illustrating the effect of toxins in a terminal artery area. The toxins may produce either endarteritis of the terminal artery with exudative closure of its lumen or they may produce spasm of its walls, the end result in either case being a small area deprived of normal blood supply. This area corresponds to an area that had been supplied with blood by any given terminal artery. In the midgut district a small anemic area of this sort loses its enzymic protection against digestive and microbic processes to a greater or lesser degree. This means that it may be attacked on the one side by digestive ferments or microbes, and on the other side by excessive production of antibodies which are capable of producing a lysis of structures in the involved area. (Turck.)

Some of us would speak of this process in mechanistic terms but perhaps we may better speak of it in chemical terms as being more comprehensive because chemistry has been described as "everything that is going on."

In regard to our second salient point, elective affinity for different toxins, the ones which appear in the midgut area may vary in character in such a way as to cause quite different types of ulcer demonstration. For example, toxalbumin from a burn of the skin or cytose from the developing ovum in a pregnant woman may cause ulcer to appear in the duodenal area. Duodenal ulcer in these patients is perhaps overlooked more often than it should be in view of the physician's attention being attracted toward more obvious features of the case. On the other hand, antigens from foci of infection in tonsils, teeth or colon may cause ulcer formation much

*Read at the San Francisco Meeting of the American Therapeutic Society, June 23, 1923.

more frequently in the affinity area of the pylorus.

Various peripheral irritations may have a precipitating effect rather than a causative effect in the production of ulcer in the midgut area. For example, correction of nasal hypertrophies or of eye muscle imbalance, the removal of hemorrhoids or of a fibroid appendix, or even the fixation of a loose kidney may interrupt the cycles or quite prevent the development of gastric ulcer in otherwise susceptible patients. Peripheral irritations are perhaps to be best looked upon as precipitating factors rather than as causative factors in midgut ulcer production.

The prompt disappearance of midgut ulcer in some patients after removal of peripheral irritations seemingly quite far removed, for example, correction of eyestrain or the closure of a hernia, would indicate the original presence of a disturbed sympathetic system which was causing wrong hormone production in the midgut area. This wrong hormone production leading to hyperacidity and to functional derangement of the intimate ganglia of stomach or bowel wall might allow more fundamental factors in the production of midgut ulcer to develop. That is what I mean by expressing the belief that peripheral irritations act as adjuvant or precipitating factors rather than as causative factors in these cases.

Concerning our third salient point, sensitization, certain individuals who have been sensitized in some way may subsequently become immune and recover from the tendency to develop midgut ulcers. Up to the present time this seems to have occurred along lines of a natural immunizing process, although the gastroenterologists are inclined to give credit to their diet lists instead. So far as I am aware direct efforts at securing immunization against a particular antigen are not as yet a feature of the everyday practice of physicians in these ulcer cases.

TREATMENT

What is to be our line of treatment? Midgut ulcers belong particularly to the internist rather than to the surgeon. The surgeon is a therapeutic resource to be made use of by the internist under certain conditions. I have sometimes operated upon two or three gastric or duodenal ulcer patients at a single clinic for the purpose of demonstrating different methods of operative technic. My latest conclusions are that most of these patients should not have been operated upon at all. On the other hand, internists who depend upon their diet lists and routine methods of treatment without going at the fundamental factors in a case are not up to date. Internists who fail to hunt up foci of infection or to make food sensitization tests or to have peripheral irritation factors removed are not to be trusted with the responsibility of the care of these patients.

Periodicity of the appearance of acute symptoms in many cases of midgut ulcer belongs to the well known law of action and reaction. Cyclic appearance of pyloric ulcer in any given case belongs in category with the cyclic rise of temperature in cases of plasmodium infection. The greater length of time in the ulcer cycle does not take it out of the physiological rôle played by antigens and antibodies.

Many of these ulcer patients who have been sent to me for surgical operation have not been operated upon. The only thing that I have cut off has been the diet list. The patients are frequently half starved and their attention has been so concentrated upon fanciful methods of medical treatment that introspection has made hypochondriacs of people who should have had ruddy cheeks and a hopeful and courageous outlook upon the affairs of life.

The search for an antigen which is causing midgut ulcer includes the idea of very high class management and the antigen is sometimes found suddenly as a surprise. In one case in which tests for various protein poisons had been made without result, the patient unexpectedly showed violent reaction to tests for wheat and was easily cured when wheat products were removed from the diet. The surprise in this endoderm case corresponded to that of a case in which chronic psoriasis involving the ectoderm was promptly cured after the patient had responded to tests for yeast sensitization.

In former years I entered with zeal upon operative treatment in midgut ulcer cases and in fact furnished one encyclopedia with its article upon the subject. Later when the American College of Surgeons introduced methods of standardization into the hospitals and the followup system was instituted we began to learn that patients who had been operated upon for ulcer and whom we supposed to have been cured had not always returned to their original advisers. They had gone elsewhere upon recurrence of symptoms.

We may ask ourselves the question why it is that any midgut ulcer patients remain permanently well after operation which makes no change in the original conditions which had led to ulcer formation. A ready answer might be that a sufficient number of antibodies remain to protect the patient against recurrence of ulcer in very much the same way as they remain to protect a patient against a second attack of typhoid fever.

Furthermore, some of the patients who refused to follow my advice to have surgical work done became quite well under the care of competent internists. These doctors convinced me with great difficulty because I was so "set in my ways," but the change in point of view has finally come about as a result of their teaching by means of object lessons.

At the present time my own midgut operative work is confined principally to ulcer cases with old adhesions which inhibit peristalsis, to old indurated ulcers which have failed to make good enough response to medical treatment and to cases with acute perforation. These form a comparatively small proportion of cases on the whole.

Concerning the first group, cases with old adhesions causing interference with peristalsis, I greatly disapprove of the attitude of internists who keep these patients going half well and half ill for years. The "cobwebs in the attic of the abdomen" should be removed when we secure good radiographic evidence of their injurious effect in any given case. No comment is required upon the group of cases in which old indurated ulcer fails to make satisfactory response to medical treatment. In the group of cases with acute perforation and penetration of protective walls I have taught heresy for many years. In this field of work the principles of the fourth or physiological era of surgery come into full play as opposed to the principles of the third or pathological era of surgery.

In the third or pathological era we were trained to do ideal work in technical operative procedure and to remove from the operative field all sources of infection. In perforating ulcer cases this meant thorough closing of the field in which escaped gastric contents appeared and it included the idea of closure of the perforation with perhaps a gastroenterostomy in addition. The fourth or physiological era includes quite a different idea. We depend upon the protective forces of the individual rather than upon our beautiful surgical art.

What are the conditions present in a case of acute perforation? There is perhaps shock or collapse. Escaped contents of the stomach are free in the peritoneal cavity and are being distributed by peristaltic movement. The patient is in no condition for an ideal operation. Attempts at cleansing the peritoneal cavity would result in causing more shock to the great central sympathetic ganglia without the remotest possibility of the surgeon being able to remove all of the escaped material. My choice of procedure has been that of the two or three minute operation followed immediately by the Alonzo Clark opium treatment. The patient is given part of a glass of methylene blue solution in advance of operation and a full dose of morphine. The methylene blue will escape through the perforation and give us its location when the abdomen is open. The dose of morphine lessens the destructive impulses which are being shot into the centres of consciousness of the patient and it halts peristalsis which is spreading escaped material. The abdomen is quickly opened and a drainage tube inserted down to a point near the perforation but not reaching quite to it. Some loops of iodoform gauze are placed in such a way as to allow freedom of escape of stomach material into our external dressings. A few sutures may be taken quickly in order to lessen the size of the surgical incision but these must not interfere with free drainage. The Alonzo Clark opium treatment is then instituted for a few hours. The patient's respiration rate may be carried down to ten or twelve to the minute by means of tincture of opium or opium powder dropped upon the tongue. The dictum of Dr. Clark was "Do not measure the opium, measure the respiration rate." The respiration rate in itself has no meaning excepting that it parallels the peristalsis rate. When the respiration rate is twelve a minute peristalsis has practically ceased and nature, rushing antibodies to the region, becomes actively engaged in walling off the area soiled by escaped gastric contents. Weeks or months later when the patient is in good physical condition an ideal operation may be done in the case provided that it becomes necessary. As a matter of fact, spontaneous closure of fistulæ will usually occur if they are not kept open by the use of antiseptics, the most injurious of which being, perhaps, peroxide of hydrogen.

Surgeons in general are not quite ready to accept the principles of the fourth era of surgery in these cases. They have spent too much time and thought conscientiously in developing the principles of the third era of surgery. At surgical society meetings my position is often attacked strongly by excellent surgeons who advocate third era treatment in these cases.

Sometimes I learn of cases of acute perforation in which an ideal operation consuming less than an hour of time is followed by the death of the patient shortly after his removal from the table. It would be unwise to say that fourth era treatment would have saved the life of any given one of these patients but a three minute operation is the treatment that would have been employed in place of third era method by some surgeons in some of these cases.

On the whole, my latest conclusions are that both internists and surgeons will become sufficiently modern in their treatment of midgut ulcer cases when the principles of the fourth or physiological era in both medicine and surgery have become well established. Meantime, I would ask the members of our society to keep in mind the three salient points which seem to me to be most important: terminal arteries, elective affinity for toxins, and sensitization. Furthermore, I would ask you all to remember the saying that it takes nine specialists to make a doctor. There are few positions in the practice of medicine in which the saying is more true than it is in connection with the subject under discussion.

The Present Status of Knowledge of the Transition of Gastric and Duodenal Ulcer Into Cancer*

CLEMENT R. JONES, M.D., F.A.C.P.,

Pittsburgh, Pa.

Does simple benign ulcer of the stomach become malignant with a frequency which should give such a complication a prominent place in prognosis? Writers as early as Cruveilheir, and Zenker suggested such a development as originating in ulcer of the stomach. (I have included ulcer of the duodenum in this discussion, on account of its close relation to ulcer of the stomach.)

An important point to consider before we are able to interpret clinical or pathological data is what evidence must we have of such a change. MacCarthy states that, "No one should state positively that cancer arises from chronic gastric ulcer until one experimentally produces chronic gastric ulcer and produces cancer in the ulcer, and then shows that all the conditions of the experiment are comparable to the condition which arises in human beings." He classifies ulcer of the stomach as: 1. Simple acute

*Read before the 1923 meeting of the American Gastroenterological Association, Atlantic City, N. J.

peptic ulcer. 2. Chronic ulcers which are tuberculous or syphilitic. 3. Chronic ulcer, the exact etiological factors of which are unknown. 4. Chronic ulcer in which there is a neoplastic process in the borders of the mucosa. 5. Gastric ulcer which shows carcinoma, not only in the borders, but also in the base.

If simple gastric ulcer of the punched out type changes to ulcer of the chronic variety, and it is simple peptic ulcer that we most frequently meet clinically, ulcers which are common in the adolescent and young adult, those under the cancer age, and if it later changes to cancer, then it should be demonstrated by laboratory and clinical methods.

There have been apparent misunderstandings of the terms simple acute ulcer and chronic gastric ulcer. A report of a pathologist of a percentage of cancer in a series of chronic ulcers of the stomach is understood by many to include the most common of all gastric ulcers; simple peptic ulcers which rarely come to the pathologist's observation except in cases of perforation. The low percentage of cases observed clinically showing malignancy years after treatment by gastroenterologists is due, no doubt, to the very great number of simple gastric ulcers treated, and the relatively small number of the chronic type. The reporting of high percentages of malignant ulcers have, we believe, resulted from a study of chronic ulcer material coming to the pathologist in large clinics and hospitals, which material includes a high percentage of ulcerating cancers.

If there is cancerous development in benign ulcers, simple peptic ulcers, the clinical reports show a much lower percentage than many have been lead to believe, and the actual percentage is probably not much greater than the almost negative findings of many good clinicians.

The impression that a patient suffering from simple peptic ulcer is in any considerable danger of developing cancer as a result will not be gleaned from the literature if it is carefully sifted for facts.

In order to get a larger amount of data than was available from my own records, I sent out a questionnaire which is as follows:

QUESTIONNAIRE

This questionnaire is sent out in order to secure data from gastroenterologists who have treated a considerable number of cases of gastric and duodenal ulcer.

1. What percentage of your cases of gastric and duodenal ulcer treated five to ten years ago have since developed malignancy of the stomach or duodenum?

2. What percentage of your cases of gastric and duodenal ulcer treated ten to fifteen years ago have since developed malignancy of the stomach or duodenum?

3. What percentage of your cases of gastric and duodenal ulcer treated fifteen to twenty years ago have since developed malignancy of the stomach or duodenum?

4. What percentage of your cases of gastric and duodenal ulcer treated twenty to twenty-five years ago have since developed malignancy of the stomach or duodenum?

5. What percentage of your cases of gastric and duodenal ulcer treated more than twenty-five years ago have since developed malignancy of the stomach or duodenum?

6. What percentage of your cases of cancer of the stomach or duodenum gave a history of ulcer symptoms covering a period longer than five years?

7. What is your conclusion from clinical observation as to the frequency with which malignancy follows gastric and duodenal ulcer as a pathological sequence?

EXPRESSIONS OF OPINION

Max Einhorn says: "It is my impression that cancer develops upon the base of an ulcer quite rarely, perhaps in about five per cent. of gastric ulcer. In duodenal ulcer, I have seen a cancer develop about nine months after gastroenterostomy in one single case."

Frank Smithies says: "In answer to question number seven, it is possibly an infrequent occurrence but does happen. No one can tell, given any proved gastric ulcer, whether it will heal, continue chronic but benign, or rapidly or slowly undergo malignant hyperplasia."

M. W. Rehfuss reports from one to two per cent. of cancer of stomach developing subsequent to treatment. He says that not more than twenty-five per cent. gave a history of ulcer symptoms over a period of five years. He states: "I feel certain that some ulcers become malignant, probably about five per cent. Malignant duodenal ulcers are extremely rare."

Kaufman states that in a very large number of true gastric cancer cases a remarkably small percentage give a history of previous gastric ulcer, or any gastric disturbances whatever.

Horace W. Soper, of St. Louis, says that in a gastrointestinal clinic he has seen no cases of gastric or duodenal ulcers become malignant.

Julius Friedenwald, of Baltimore, estimates about five per cent.

Alvarez says: "I saw very few gastric ulcers where they turn out to be malignant. I believe they have generally been malignant before I saw them."

B. B. Vincent Lyon's statement is: "My personal experience leads me to believe that the tendency to cancerous development of old gastric ulcers is less common than I would be led to believe has been the experience of a number of other observers."

G. W. McCaskey, of Fort Wayne, states: "When a diagnosis of ulcer was made and malignancy was later found, I think it was present but not demonstrable at the first examination. I think the transition occurs but rarely."

A. E. Austin, of Boston, says: "My experience is that if cancer follows ulcer it occurs within five years and in those between forty and fifty years of age."

Richard C. Cabot, of Boston, has seen no case developing malignancy under any of these classifications; has seen no cases of cancer of the stomach with previous ulcer symptoms over the five year period.

John L. Kantor: "In my personal opinion the reason that some believe that ulcers change to carcinomas is twofold: First, pathologically a carcinomatous ulcer may give the superficial impression that it is a simple ulcer undergoing malignant degeneration. This is purely inferential, however. Secondly, it is possible that the duration of some types of carcinoma has been grossly underestimated. I note that you set a limit of five years. Why can't a carcinoma go on for this length of time with symp-

toms, and possibly longer still without symptoms? In short, what evidence is there that a carcinoma or carcinomatous ulcer has not alway been such from the start?"

Harlow Brooks, of New York, reports from four to five per cent. and adds, "My opinion as regards relation between gastric ulcer and carcinoma have undergone a radical change. I doubt very much if any real relation exists."

The foregoing are not only answers to my questions, but an expression of opinion on the part of gastroenterologists of years of experience which has confirmed an opinion long held by me that nearly all, if not all, of the cancers supposed to have developed on the base of old or chronic ulcers, were in fact malignant ulcers from the beginning.

The etiology of chronic ulcer of which some writers state from sixty to seventy per cent are malignant is limited to syphilis, tuberculosis, ulcers of unknown origin and carcinoma.

Many of the cases of malignant disease of the stomach show no evidence of the condition until near the last stage of the disease. We have no means of knowing how slow these chronic malignant ulcers may be in reaching a point where diagnosis of a cancer may be made and the history of many cancer cases is that the patients live from one to three years after diagnosis of cancer has been made.

For many years we have been striving for a means of early recognition of cancer in the viscera, but up to the present it is necessary in all early cases and many late ones to wait for the report of the pathologist. This being the case, it seems to me that the only way to approach this question for practical clinical purposes is to consider those cases in which a diagnosis of ulcer of the stomach has been made years ago and in which the irritation stressed by many writers had probably persisted, and by a series of questions mailed to gastroenterologists, gather additional data, for careful consideration, from these specialists who have probably seen a much larger number of cases of ulcer of the stomach than has any like number of clinicians.

Their report based on clinical observation of the frequency with which malignant changes have occurred in gastric ulcer is evidence well worth while. From the nature of the problem, it is certain that any error will favor the positive rather than the negative conclusion. Gastrointestinal disturbances are more frequently due to other causes than to ulcer and a history of dyspepsia taken at the time of a diagnosis of cancer of the stomach might easily be mistaken for a history of ulcer when in reality it is not. The stomach may be definitely predisposed to malignancy in many individuals. The duodenum as a primary seat of cancer is probably cancer proof. I have only observed it involved as an extension of a neoplasm from the pylorus or the biliary tissues.

We are confronted with the question: Does an ulcer of the chronic type, where it is of such size (two and a half cm. in diameter) as to be demonstrable with the x ray, definitely change its character? Do ulcers of syphilitic, tuberculous or unknown origin take on cancerous development? Does irritation add cancerous growth to the syphilitic, tuberculous or the type of unknown origin? These changes are, I believe, possible.

While we know that malignant neoplasms ulcerate, we have, nevertheless, no proof positive that ulcers take on malignant development. A number of clinicians who have treated many cases of ulcer of the stomach and duodenum, are not certain that a single case treated in their clinics has since developed cancer, and others a possible one to five per cent. All these reports come from medical clinicians who have not resorted to surgery to prevent cancer formation in ulcer or scar and thus possible cases of cancer development would be greater among this group of cases if any such change occurred.

It is a mistake to speak of the degeneration of ulcer into cancer, because if such change does take place, it is not degenerative. Cancer is a constructive process—a purposeless one—a functionless new growth—a development of cells without function which later break down, but the beginning of such a growth should not be spoken of as a carcinomatous degeneration.

In the study of the data obtained by this questionnaire it is evident that most of us are not quite sure but that all of the cases of cancer of the stomach due to ulcer may not have been malignant from the beginning of the condition and symptoms considered those of ulcer may have been caused by the early stages of the malignant process. The time necessary for changes in the tissues of the stomach are of extreme variation; some develop slowly and others very rapidly.

There is a distinct lack of harmony among pathologists as to just what is to be considered as sufficient evidence to establish a cancer as having resulted from a primary benign ulcer. The finding of both ulcer and cancer in the same stomach is not proof that the latter was caused by the former. The incident of a cancer in a stomach which has in the past been the seat of ulcer is in no way conclusive unless we find a greater percentage of patients with cancer of the stomach who have had an ulcer, the benign character of which has been definitely settled, than the percentage of those who develop gastric malignancy without having had ulcer, that is, to reach such a conclusion from the clinical data one must know that a larger number of cases of cancer of the stomach occur in ten thousand proved cases of benign ulcer of the stomach than from ten thousand persons with no ulcer. The data I have been able to collect lead me to believe that no such evidence could be produced.

No previous history of gastric disease or a very short period of gastric symptoms prior to the beginning of the present cancer symptoms which date back six months to two or more years is the usual history.

CONCLUSIONS

1. The change of gastric ulcer of a benign origin into cancer is difficult to prove.

2. The evidence of the laboratory is not conclusive.

3. That cancer of the stomach is so far as we know not usually a transformed benign ulcer.

4. Reliable statistics do not support the contention that cancer of the stomach is more frequent in patients who have had benign ulcer than those who have not.

A Case of Megacolon*

MARKS S. SHAINE, M.D.,
New York

Megacolon is a rare disease. Up to 1897 there had been only twelve recorded cases and only twelve more between 1897 and 1899, though at this time the disease had been well recognized and understood. With the increased frequency of x ray examinations in gastrointestinal cases the number of cases of megacolon reported rapidly increased, yet in 1921 Ladd could collect only 118 cases from the literature.

In their recent paper on megacolon (1), Fowler, Davidson, and Mellon have reviewed the history of our knowledge of the disease in such a thorough and complete manner that only the briefest résumé need be given here.

ETIOLOGY OF MEGACOLON

There is no general agreement as to the nature of the disease. Hirschsprung, who wrote the first good description of the condition in 1886, believed "that the evil lying at the root must be considered either as an anomaly of development or a pathological fetal process."

The disease has been variously attributed to obstruction, to a neuromuscular defect and to valve formation, also to unusual length of the sigmoid with kink formation, angulation, dilatation and hypertrophy. Hypertrophy is not found at birth but develops subsequent to the kinking and volvulus.

Spasm at the rectosigmoidal junction or at the anal sphincter have also been considered as the cause of megacolon. Meyers cured five out of six cases of constipation in children who had redundant sigmoids and one of whom had megacolon by the administration of atropin.

In the opinion of A. Hurst the disease is due to obstruction, which in turn is due "to achalasia or the absence of the active relaxation of the circular muscular fibres at the pelvirectal flexure when, at the commencement of defecation, a peristaltic wave passes down the pelvic colon into the rectum." The obstruction leads to hypertrophy and dilatation above it.

To my mind this theory cannot explain the well known fact of the occurrence of megacolon in the newborn and in the fetus. The fetus retains the meconium until birth (except in cases of fetal death, where the relaxation of the anus allows it to escape into the liquor amnii). The amount of meconium is small and produced very slowly; the intestinal contents are sterile and there can therefore be very little, if any, gas formation; it is therefore difficult to conceive that even with an obstruction there can be sufficient and prolonged enough peristalsis to produce the great redundancy and dilatation seen in the cases of congenital megacolon.

As just stated the disease has been found in the newborn and in the fetus. It is most commonly seen in infants, less frequently in adults. Hurst had a patient aged sixty-five and Herringham operated on a man of seventy-three.

The upper limit of the dilatation is usually in the sigmoid and descending colon, but never in the small bowel. The dilatation usually extends downwards to somewhere in the last three inches of the pelvic colon.

The history is usually of constipation beginning early in life. There are frequent attacks of abdominal pain with distention, sometimes with vomiting, which last from one to three days, which are relieved by a movement of the bowels which requires one or more enemata to bring about.

DIAGNOSIS

The diagnosis can usually be made from the history, from the abdominal distention and from the percussion of the dilated bowel, and also by a proctoscopic examination, from the ease with which the instrument can be introduced and the distance within the bowel that can be reached by it. X ray examination either by ingested meal or by barium enema will disclose the condition at once. Sooner or later in these cases complete obstruction develops, requiring operative treatment.

REPORT OF CASE

My patient, Jerry C., was thirteen years old. He was a full term baby, weighed eleven pounds at birth, and was nursed by his mother for ten months. He had measles and whooping cough in early childhood, otherwise he was well till the onset of his present trouble, at the age of nine. Up to this age his bowels had been moving daily but at this time he began to suffer from constipation. He had frequent attacks of pain in the abdomen in the region of the splenic flexure which would last from twenty-four to thirty-six hours. During an attack he would vomit several times. The pain occurred at intervals of one, two or three weeks and would last until by repeated enemata he would have a good movement of the bowels. Sometimes an attack could be averted by the administration of a warm enema. The attacks would leave him weak and compel him to remain in bed for several days. He had been in the habit of taking laxatives and enemata frequently. He was anemic and below weight. His circulation was poor; his hands cold and cyanosed. The chest was negative. The abdomen was greatly distended, and the descending colon could be mapped out by percussion.

A barium enema was administered and the patient x rayed.

The röntgenograms show the enormous dilatation of the colon from the rectum upwards to the middle of the transverse colon. Whereas in a normal adult one quart of barium mixture will fill the whole colon from rectum to cecum, in this boy three pints filled it only to the transverse colon.

I referred the patient to Dr. Jerome M. Lynch who was kind enough to give me the following report of the proctoscopic findings and also of the operation which he performed at St. Bartholomew's Hospital on July 18, 1922.

On passing the proctoscope into the rectum, one

*From the service of Dr. John L. Kantor, Department of Gastroenterology, Vanderbilt Clinic, Columbia University.

was immediately impressed with the enormous dilatation of the rectum and the varicosity of the rectal veins. The instrument passed into the sigmoid easily for a distance of thirty-five cm. The patient was then placed on his back, and on palpating the abdomen, the top of the proctoscope could be felt under the ribs about ten cm. above the umbilicus. I am sure

Fig. 1.—Röntgenogram of patient in a case of megacolon after opaque enema.

one could have passed a 40 to 45 cm. proctoscope before reaching the apex of the sigmoid.

The mesentery of the small bowel was studded with enlarged glands. This condition was exaggerated in the mesocolon. The appendix ran along the outer border of the colon as far as the lower border of the right kidney, plastered on a mesentery covered gland. The most marked gland enlargement followed the course of the colic artery, up as far as the duodenum. The glands were matted together and formed a tumorlike mass that one usually sees associated with tuberculosis. The sigmoid was enormously elongated to two or three times its normal length, and aboral to apex was a small pearshaped tumor. The urachus was present and patent.

An appendicostomy was performed with a resection of twenty-five cm. of sigmoid. End to end anastomosis drain inserted. Appendix brought to wound and catheter passed through lumen. Wound closed in layers.

PATHOLOGIST'S REPORT BY DR. A. F. COCA

Specimen consists of a portion of intestine about fifteen cm. in length. The wall appears somewhat thickened but shows otherwise no gross abnormalities. Accompanying the intestine is a portion of tissue of about the size of an almond, said to have been attached to the mucous surface of the intestine. The examination of the cut surface of this portion of tissue reveals a considerable infiltration of blood. The section of the intestinal wall shows no pathological changes. Those of the accompanying portion of tissue show the glands to be irregularly distributed through a connective tissue that is the seat of an acute inflammation characterized by leucocytic infiltration. Many of the glands are greatly dilated (almost cystic). The sections were submitted to Dr. James Ewing, of Cornell Medical College, who considered the process to be nonmalignant—perhaps not even truly neoplastic.

I saw the patient again eight months after the operation. He looked well, had gained eleven pounds, had not had a single attack of abdominal pain, and his bowels had been moving daily without having had to resort even once to an enema or a laxative.

CONCLUSIONS.

I believe this case is worth reporting because the disease is interesting and uncommon; because there

Fig. 2.—Röntgenogram of patient six hours after the ingestion of barium buttermilk meal. The enormous distention with gas of the splenic loop can be seen. The stomach is pushed far down and to the right.

are not many cases recorded of complete cure by operation; because it was accompanied by a marked and widespread enlargement of the mesenteric glands; and lastly, because, as there is as yet no general agreement as to its cause, our knowledge of the disease can only grow by the study of more and more cases, especially those that come to operation or necropsy.

The Investigations and Management of Cases of Suspected Gastric Carcinoma

WILLIAM VAN VALZAH HAYES, M.D.
New York

The most common form of cancer is gastric carcinoma. According to Hoffman's (1) estimate, the mortality from cancer in continental United States in 1915 amounted to over eighty thousand, and of these thirty-nine per cent. died of cancer of stomach and liver. He also stated that the cancer death rate was increasing at the rate of about 2.5 per cent. per annum. According to the returns compiled by the Census Bureau more than seventy-six thousand deaths from cancer occurred in the death registration area of the United States during 1921, and the probable number of deaths from this cause in the entire United States during 1921 was ninety-three thousand.

The tremendous and increasing mortality indicates widespread errors in diet and hygiene. It is manifest that in spite of all that has been said and done to bring about the early recognition of gastric carcinoma, comparatively little has been accomplished as yet. How many busy surgeons can record more than one or two of their patients living nine or ten years after operation for gastric cancer? Not until the laity are better informed and not until every physician has the haunting dread that *he* may be the man to permit some one to go to needless death, can we hope for proper progress.

In 1919 Deaver (2) published the statement that "cancer of the stomach—is perhaps the most insidious or at least one of the most insidious diseases we have to deal with, and one in which early diagnosis is so desirable and yet so rarely made," and urged the advisability of exploratory laparotomy in suspected cases.

Cole (3) insists "that in order to detect (gastric) carcinomas at an early stage all patients past forty years of age with even slight gastric symptoms must be examined röntgenologically (serial method) if the lesion is to be detected at a stage when a recognition of the condition is still of some value to the patient."

Friedenwald (4) in a most interesting analysis of one thousand cases of cancer of the stomach, found loss of weight in 98.5 per cent., pain in 93.1 per cent., anorexia in 89.3 per cent., vomiting in 89.3 per cent., tenderness in 89.3 per cent. He found occult blood in ninety-three per cent. of 216 early cases.

Ewing (5), quoting Zoeppitz, states: "Zoeppitz points out the nearly constant occurrence of ulceration or erosion in early lesions, and estimates the frequency of early symptoms as follows: occult blood eighty-five per cent., emaciation 89.9 per cent., anacidity 88.9 per cent., lactic acid 67.3 per cent., long bacilli 64.4 per cent., papable tumor 63.4 per cent."

With continuing gastric disturbance in any one past thirty years of age, the possibility of carcinoma should be considered, and careful investigation, including x ray examination, preferably by the serial method, if possible, should be made.

In considering a given case it is well to look into as many of the following details as may be necessary either to make the diagnosis clear or at any rate determine whether or not surgery should be advised.

1. Is there a history of indigestion coming on rather suddenly in a patient aged thirty or more whose previous digestion has been good; or has a patient with chronic indigestion suddenly without due cause begun to be worse?

2. Is there a steady loss of weight in spite of an apparently sufficient diet?

3. Is there persistent anorexia?

4. Is there vomiting without manifest cause?

5. Is there chlorotic anemia, progressively worse? Remember that the blood may be concentrated from defective absorption of liquids.

6. Is there impaired gastric motility as shown by food stagnation, determined by use of stomach tube or x ray?

7. Is there diminution or absence of free hydrochloric acid in the gastric contents, forty-five to sixty minutes after giving bread or a roll (seventy gm.) and plain water (350 c. c.)? In the absence of free hydrochloric acid, the presence of lactic acid (with a previous milk free diet) and the Boas-Oppler bacilli suggest the existence of cancer. As is well known—absence of free hydrochloric acid is not pathognomonic of gastric cancer; and on the other hand the hydrochloric acid may be excessive—presumably in the cases developing in ulcer near the pylorus.

8. Is there occult blood in stomach contents and stool? The test for hidden blood in the stool should be made in every case of subacute or chronic indigestion, care being taken to exclude blood from hemorrhoids or rectal ulceration. When the patient shows occult blood and is put to bed, given a nonstimulating liquid and soft diet, is kept free from gaseous distention and superacidity and given as much as a drachm daily of bismuth subnitrate; or if in suitable cases duodenal feeding be employed for two to four weeks, all evidence of occult blood should have disappeared from the stool by the sixth or seventh week at the latest. Persistence of occult blood beyond this period is highly suggestive of malignancy.

9. Does a positive "thread (6) impregnation test" fail to become a negative one under proper treatment? A definite blood stain at a definite point on the thread in repeated tests is evidence of a pathological condition. This may indicate nothing more than erosion or congestion, but one should not rest content until this test becomes negative.

10. Is there the suggestion of increased resistance in some portion of the stomach on careful palpation as the semireclining patient lowers and then relaxes the diaphragm? A small palpable tumor does not necessarily indicate that the case is hopeless, or even that a cancer exists.

11. Is there syphilitic infection? A Wassermann test is always desirable, and if positive, prompt and thorough antisyphilitic measures may be employed

for a brief period before reaching a positive diagnosis.

12. Finally and perhaps the most important of all, is there a characteristic filling defect, or deformity or localized impaired peristalsis in the stomach wall, or pyloric obstruction as shown by x ray examination? If the pictures are properly taken and interpreted by an able, experienced operator, a definite diagnosis can be made in the great majority of cases. As between indurated ulcer and cancer, the latter is characterized by a much more irregular contour. Fluoroscopic examination, while less accurate than the serial photographs in the writer's judgment, is used with great success by some physicians; and owing to the slight expense and general availability is sure to be used more and more. The day may come, and may it come soon, when every one suffering from gastric indigestion, even moderately prolonged, will be examined by the x ray. When this is attained, if only approximately, there should be a marked improvement in the mortality from gastric cancer.

Fig. 1.—Case III. Indurated ulcer (probably cancer) on the lesser curvature.

Whatever is done or omitted in these cases one should not fail, 1, to make the test for occult blood in the stool, and 2, to insist on careful x ray study.

If for any reason it is impossible to make a positive diagnosis promptly, the patient should be given suitable medical treatment under close observation. Definite improvement should take place in six or possibly seven weeks. This is especially important in differentiating bleeding ulcer from ulcerating cancer. If the blood in the stool does not disappear after four to six weeks of proper treatment, it is pretty certain cancer is present.

The following histories may prove of interest in this connection:

Fig. 2.—Case VII. Annular tumor of pylorus. Stomach in normal position.

Case I.—H. G., woman, forty-eight years of age, unmarried. History of indigestion and constipation for twenty-five years. Complained of discomfort after meals, lasting one and a half hours, followed by sensation of hunger. Taking milk made her feel better for a short time. Had been under a local physician's care for nineteen months and had not worked for that period. During this time was in bed in a hospital for three weeks. Physical examination showed stomach in a position of gastroptosis, its muscle lacking in tone. There was marked food stagnation with high acidity. An hour after the Ewald-Boas test breakfast, the free hydrochloric acid was 0, and the total acidity 104. There was no occult blood in the stool. The thread test showed a small, distinct blood stain near the pylorus. X ray diagnosis (Dr. A. J. Quimby): General ptosis. Adhesions of the first portion, and duodenal ulcer. Adhesions around the cecum and terminal ileum. Iliac stasis of great degree. Stasis in the ascending colon. Angulation of the transverse colon of unknown cause. The deformity about the pylorus was such that the röntgenologist thought there might be a possible growth. Operation was strongly urged by a surgeon, her family physician and myself and positively refused. This patient was put to bed in the Polyclinic Hospital and was given liquid diet and soft cereals together with suitable medication. Twenty-three days later the thread test still showed a stain near the pylorus. Later there was a gradual improvement in the patient's condition, the thread becoming negative.

For several years this patient had to be very careful as to diet, and took mineral oil regularly to avoid constipation. The weight, 99⅔ pounds, when the patient was first seen in February, 1913, had increased to 108½ pounds in October, 1913. By August, 1915, weight was 118¾ pounds. In reply to a letter of inquiry, this patient wrote on the first of February, 1922: "I am glad to say my digestion is very good, and I am able to eat a little of all foods without feeling any distress. In addition to this, I do practically all kinds of housework."

Case II.—T. W. K., a bachelor, aged eighty-two years. He had been living in hotels and restaurants, and eating unsuitable food. Stated that he had an attack similar to the present one, i. e., indigestion, distress and anorexia, twenty years previously and then felt fine until one month ago when he began to have dull epigastric pain; a sore feeling in the epigastrium; anorexia, nausea and sour vomiting for the past five or six days. The day the patient was seen at five o'clock he had taken no food all day. On physical examination nothing definite was found except marked gaseous distention of stomach and bowels; blood pressure 170-84. This patient was put to bed for observation in the New York Hospital, and owing to his age, temperament, and condition, no thorough investigations were undertaken at first to clear up the diagnosis, but it was feared malignancy might be present. Notwithstanding the fact that the patient was kept quietly in his room and given liquid and soft cereal diet, on the night of June 25, 1920, the patient, after getting out of bed, fainted and had a hemorrhage from the stomach, estimated by the house physician to be about eight ounces. Later there was marked melena. With rest in bed, a liquid diet and suitable medication, gradual improvement took place, but the stools were not free from occult blood until after August 12th, about seven weeks.

On leaving the hospital the patient was sent for a few months to Fair Oaks Sanitarium, and slowly but steadily improved. By May, 1921, his weight was 150 pounds. By December, 1921, his weight had increased to 165½ pounds and he was leading his usual life, though careful as to diet, and feeling very well. He has continued to improve. He was (spring of 1923), eighty-five years of age and reported spending an enjoyable winter in Florida. This case was one to suggest strongly the possibility of malignancy. The improvement in his condition shown by the disappearance of occult blood and gain in weight made it evident that we were dealing with an ulcer, which was probably located in the duodenum.

Fig. 3.—Case IV. Chronic ulcer, thought to be malignant by New York X Ray and Pathological Laboratory.
Fig. 4.—Case V. Twenty-four hours gastric and colon residue. Small carcinoma at pylorus. Glands involved.
Fig. 5.—Case VI. Gastric carcinoma.

Case III.—E. V. E., woman, aged forty-six, married. Seen in August, 1912. History of indigestion for which stomach was washed when a young girl. In 1905 treated in Boston for sour stomach and gastric pain. Improved after two months. The same trouble annoyed her about eighteen months ago. Exercise would cause nausea and vomiting. Five months ago she began to regurgitate sour liquid and gas, five or six hours after meals. Now drowsy and sleepy about two hours after meals. Has pain in left epigastrium, going through to back and to left intercostal region. Pressure of corset increases pain. Palpation of stomach causes pain. There is tenderness in left epigastrium and constipation. Test meal shows acidity normal; but traces of blood present. No blood in stools.

An x ray examination by Dr. Lewis G. Cole showed "an indurated area" about two and a half inches from the pyloric sphincter. This does not have all the characteristics of malignancy. "I believe surgery is indicated," he stated. This patient was operated upon by Dr. W. A. Downes. A mass about two inches in diameter, thought to be malignant, was found high upon the lesser curvature, about one inch from cardia. Removal deemed too hazardous. Gastroenterostomy performed. This patient lived six or seven years after the operation, proving that the mass was an ulcer and not a cancer.

Case IV.—M. F. C., an unmarried marine engineer, aged thirty-two. Referred by Dr. C. W. Oakes for diagnosis, February 23, 1923. Has had trouble with his digestion off and on for sixteen years. Annoyed by gas in stomach and food did not seem to pass through it properly. At times regurgitated food and tasted it six or seven hours after eating. Had pretty constant pain in the epigastrium, running through to the back. One month ago for a period of four days vomited after eating. Pain worse about one hour after meals; may be worse after a light meal than after a heavy one. Eating diminishes pain for a time. Has lost ten or fifteen pounds in weight.

The patient had brought with him x ray pictures of the stomach and a report on them by Dr. John L. Cornish as follows: Stomach: "There is a filling defect seen at the greater curvature of the stomach in the pyloric portion which is persistent and can be seen on all the radiographs. The pylor portion appears narrowed and irregular on both t greater and lesser curvatures." "There is radi graphic evidence of a large gastric barium resid after six hours." "The radiographic evidence poin toward the presence of gastric malignancy involvi the pyloric portion of the stomach and obstructi the egress of the gastric contents." Further stu of this patient gave the following: Tenderness pylorus. Fasting contents, removed about fifte hours after a light supper including rice and raisi gave sixty-seven c. c. of contents with free hydr chloric acid 21. Total acidity 32. No blood. microscopic food retention. Ewald-Boas test brea fast at 76 minutes—211 c. c. Free hydrochloric ac 28. Total acidity 74. Blood absent. Stool show no blood and nothing else of definite significanc Thread test, negative for blood. Hemoglobin per cent. Red cells normal. Wassermann—neg tive.

The patient was returned to Dr. C. W. Oakes wi the diagnosis: "Chronic ulcer of stomach" and oper tion advised. Operation March 9, 1923, by Dr. Jo F. Erdmann, who found an indurated ulcer in fir portion of duodenum, causing marked stenosis. Th ulcer was excised and a Horsley operation performe This patient reported April 4, 1923, and was foun to be regaining weight and vigor satisfactorily.

Case V.—Mrs. R. R., aged fifty-one. Troub of five weeks' duration began with acute attack nausea and vomiting and some pain, then belching gas in the morning and after meals. Her fami physician put her on a diet of milk and steame gruels, later adding soups, raw eggs, bread and bu ter—with relief of symptoms.

A physical examination of the patient showed h to be fat and florid and with a systolic murmur base of heart and transmitted up and to right. Sto ach gave succussion. Digestion was prolonge There was no tenderness. Palpation difficult becau of adipose tissue. Examination of stomach show a large amount of stagnant three layer content One half solids. Free hydrochloric acid 8. Tot acidity 52. No blood. Hemoglobin 86 per cen Red cells normal. Urine small amount. Albumi No casts. No blood in stool. X ray by Dr. A. Quimby. Diagnosis—"Gastric delay of unusual d

ree, twenty-four hours, due to stenosis in the first ortion of the duodenum. Pyloric deformity due malignant infiltration of the extreme lower portion of the antra pylorica. Redundant sigmoid. tasis in the sigmoid." This patient was referred romptly by her family physician to a surgeon who ound a mass the "size of an almond" with enlarged ands, and performed a gastroenterostomy. I was ot present at the operation but have never ceased to gret that more radical surgery was not undertaken. his is the type of gastric carcinoma that should furish the greatest percentage of complete cures.

Case VI.—J. H., aged forty-eight, married, came nder observation at the Polyclinic Hospital the fall f 1912. For six months patient had been steadily sing weight and strength and suffering from modately annoying indigestion. Weight 103. A mass pproximately the size f a hen's egg could be elt near the umbilicus. ray showed an irregular filling defect on reater curvature, pyric antrum. A gastroenterostomy was performed at the Polyinic Hospital by Dr. V. S. Bainbridge, November 1, 1912, the ondition of the patient ontraindicating a complete operation. In late ecember the cancer ith the right end of ie stomach, a portion the duodenum, a portion of the pancreas, id also some enlarged ands were excised by ie same surgeon. The atient made an uneventful recovery, and ent back to work, first expressman and later doorman in an apartent house. He reorted March 4, 1922, oking and feeling ell. Weight 126½ ounds.

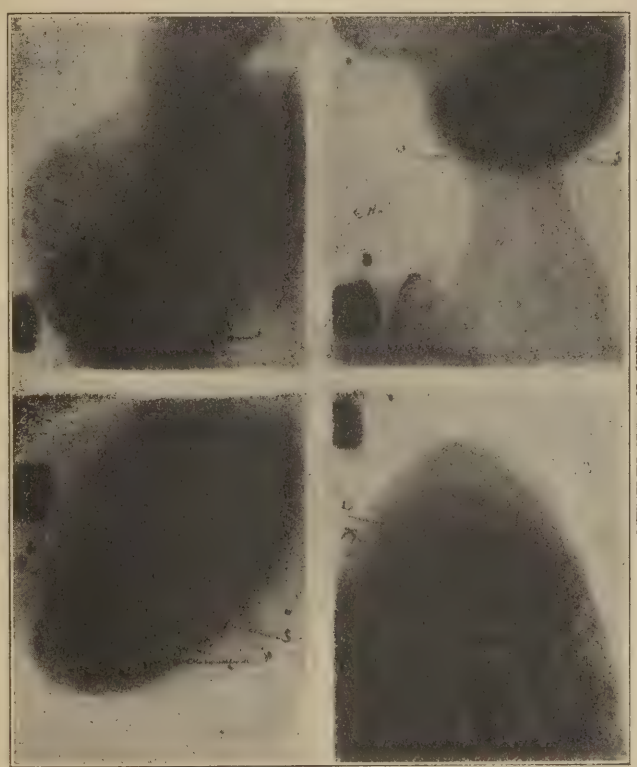

Fig. 6.—Case V. Showing very small carcinoma. Upper right x ray shows six-hour test. The upper left shows picture taken in prone position as does the lower left. The lower right picture was taken in the erect position.

Case VII.—J. H. B., woman, married. Acidy of stomach and occasional vomiting after meals ghteen years ago. Four months ago did not feel uite right. Two months ago on returning from acation began to vomit at night, usually at 2 m., sometimes later. Less frequent at first, ter nearly every night. Vomit sour and contained mucus. No blood or coffee ground material. or the past month had had daily lavage and a buttermilk diet with relief of symptoms. Had lost about ourteen pounds in the past three months. Functional examination after test breakfast showed contents one half sediment, absence of free hydrochloric cid and organic acid.

A small amount of mucus—ferments diminished. oas-Oppler bacilli absent. No blood. Three and half hours after two eggs, a roll and a glass of water, there was three layer stagnant contents. Lactic acid present. No blood. No Boas-Oppler bacilli. No blood in the stool.

X ray examination by Dr. L. G. Cole who stated: "Between the duodenum and the peristaltic end of the stomach was a space about an inch wide where the bismuth had been displaced, except for a small opening through the centre where the contracted lumen still exists. I take this to be an annular growth at the pylorus, with the worm eaten appearance which is typical of carcinoma." Prompt operation and excision was recommended. The patient was unwilling to be operated upon in New York; but a little later was operated upon by a surgeon of good standing in a neighboring state. He found no glandular involvement and did not excise the indurated mass which he believed to be ulcer, but performed a gastroenterostomy. The patient improved for a time of course, but died twenty-three months later from carcinoma.

This last case represents a group demanding special consideration and care. The operation of gastroenterostomy may be the procedure indicated, and usually results in surprising improvement in weight and strength. But we should not feel that our duty is done when this has been accomplished. If the mass in the stomach wall is due to ulcer, it should disappear almost entirely in three or four weeks after the gastroenterostomy and give a corresponding x ray picture. Should the x ray show little or no improvement in the filling defect at the end of a month, the indurated mass should be excised if the patient's condition permits.

Foreign Bodies in the Stomach

LOUIS TUFT, M.D.,

Philadelphia

Foreign bodies in the stomach, though always interesting and instructive, are by no means uncommon occurrences. Since the time of Schwabe (1), who in 1635 removed a table knife from the stomach forty-one days after its ingestion, literature has been replete with numerous examples, all bearing testimony to the infinite variety of foreign bodies that may be found in the stomach. Some of these are swallowed by the insane, others by accident, and occasionally by professional mountebanks as a means of livelihood for the amusement of the public. Buttons, coins, pins, needles, safety pins, nails, spoons, forks, stones, keys, broken glass, false teeth and dental plates, hair balls—these are among the bodies most frequently swallowed. Those swallowed by accident occur mostly in children and are usually single, smooth and round—for instance, coins or marbles. Ofttimes they may be sharp and do damage in their passage through the gastrointestinal tract, although instances have been reported of large objects, such as spoons or forks, having been expelled by the patient per rectum without any apparent injury to the patient's health. Thus in Block's (2) case, in a period of eight months the following objects passed through the rectum of an insane patient: 157 pieces of glass, the longest being two inches; 102 pins, 150 rusty nails, three hairpins, fifteen broken fragments of iron, a large piece of lead, half of a shoe buckle and three small hooks. It is remarkable indeed that so many sharp and pointed articles can pass through the gastrointestinal tract without serious consequences. Not all cases are so fortunate; the foreign body may lodge in the esophagus or stomach and perforate or lacerate the walls. Thus in a case reported by Inch (3), at operation a perforation of the stomach from a protruding pin was found. After a long illness the patient recovered.

The length of time which the foreign body remains in the stomach before discovery is quite variable. Where it is swallowed accidentally, the accident is usually reported at once and treatment instituted promptly. Among professionals and especially among the insane, the foreign bodies may be present a long time before discovery. Numerous instances are reported in the literature of a most grotesque assortment of articles being retained in the stomach for long periods without injury to the mucosa or producing symptoms. Thus Benjamin (4) in 1907 reported a case of a glass and nail eater who ate pieces of glass as big as his thumb for twenty years and swallowed eight and ten penny nails for five years. At operation fifty-two nails in various stages of erosion, and five pieces of glass were removed. The nails were in bunches and a number were embedded in the stomach wall surrounded by exudate.

The symptoms in these cases are variable. In some, there is anorexia, epigastric pain after eating food and occasional vomiting. The vomitus is tinged with blood or sometimes free hematemesis occurs. In other cases local peritonitis has occurred. The size and number of foreign bodies may have but slight effect in the production of symptoms. Thus a single small object when swallowed may lodge in the stomach or intestines and give rise to marked obstructive symptoms, whereas multiple large objects may be swallowed and only cause vague gastric symptoms that may be present a long time before becoming more acute, viz., Benjamin's case quoted above. In all obscure gastric cases with vague gastric symptoms of long duration, accompanied by weakness and emaciation, the possibility of the presence of a gastric foreign body should be investigated. In these types of cases the x ray is an invaluable diagnostic aid and the earlier it is used the sooner can a positive diagnosis be made and prompt treatment instituted. It is upon these factors, early diagnosis and prompt institution of treatment, that the prognosis depends. Modern abdominal surgery has developed to such an extent as to make removal of foreign bodies lodged in the stomach a comparatively safe procedure. The percentage of recoveries is high, even when they have remained in the viscus for a long time. The sooner the foreign body is removed, however, the better is the result likely to be.

The end results in the vast majority of cases of foreign bodies when not removed is death, either from mechanical obstructions, erosions into vital structures, or direct or indirect infection. Where the foreign body or bodies are small and blunt, it may not be necessary to operate, as the patient may pass them per rectum without any harm. He should, however, be constantly observed for signs of obstruction; if these occur it is usually advisable to operate at once. Frequent stool examinations and x ray studies should be made in order to watch the progress of the foreign bodies.

In these cases, the patient should be cautioned against the use of laxatives. A diet of potatoes, rice, cream of wheat, bread, beans and agar will assist in safely passing the object. Where the foreign body is sharp, if small it may pass through without danger and operation not be necessary, but where it is large, it is usually best to operate at once, as the danger of perforation or obstruction is obviated by the low mortality of this type of abdominal operation. In all cases of doubt, it is best to err on the operative side, for upon early diagnosis and prompt operation depends the successful outcome of these types of cases.

Case.—The patient, Mrs. C. H., was admitted to my care in the female ward, Pittsburgh City Home and Hospital, Mayview, Pa., on November 25, 1921, complaining of a right hemiplegia. She was fifty-five years of age and a widow, her husband having died of gastric ulcer and perforation of the bowel. Her family history was negative. She had one child who died in infancy and no miscarriages. She had pneumonia twice and diphtheria once. She had been

operated on twice, once twenty-five years previous for a pelvic abscess and fifteen years later had her tubes and ovaries removed. Before the onset of the hemiplegia she had done practical nursing; since then had done very little but went around from city to city interviewing physicians in an effort to cure her hemiplegia. This stroke, she stated, came on suddenly about November, 1920; since then there had been no change in her condition in spite of treatment. Aside from this she had been fairly well; at times she stated she had a little pain in the upper abdomen bearing no relation to meals and passing away in a short time. There were no other gastric complaints at this time. Her bowels, she stated, had always been constipated. She had always been more or less of a nervous temperament, and even during the taking of her history and the examination, it was noticed that she seemed disinclined to talk or to permit proper examination.

A physical examination, shortly after admission, showed the patient to be a fairly well nourished adult, white, female, rather depressed and tearful. Scattered over her body were areas of brownish pigmentation, especially over her abdomen, and areas of vitiligo. Her eyes showed a slight bilateral arcus senilis, the pupils were very small, equal and regular, and did not react to either light or accommodation. The tongue was coated and dry, but in midline and steady. The chest was negative; her heart showed no abnormalities. There was slight tenderness over the stomach region but no rigidity or midline operation below the umbilicus. Slight radial sclerosis was present. The whole right side showed evidences of a right hemiplegia, spastic in nature. The urine was negative, and blood Wassermann also negative.

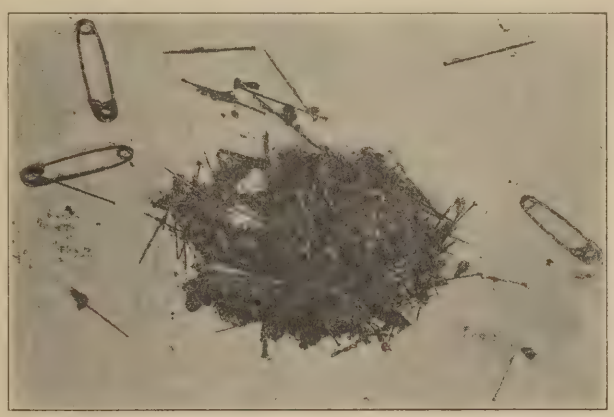

Fig. 1.—Large mass of pins removed from the stomach of patient in case reported.

On admission patient was placed in the hemiplegic ward. During her stay there she was depressed, very irritable, impudent and resistive toward the nurses. These facts, together with later developments in the case, make it highly probable that she had a psychosis, either of the involutional melancholia type or presenile dementia.

About ten days or two weeks after admission, the nurse noticed that the patient vomited slightly after meals, the vomitus containing food particles. She also complained for the first time of pain in the epigastrium and stated that her bowels had not moved for several days; because of her persistent irritability and expressed aversion to doctors, satisfactory examination was impossible and diagnosis a guess. Heat was applied to abdomen and a mild saline laxative given, but the bowels moved with difficulty. Her diet was restricted to liquids and gastric sedatives were given, but in spite of these measures vomiting continued. Enemata were but slightly effectual. The vomitus now contained small flakes resembling pieces of tissue and many blood clots. Similar material was present in the feces of the patient. It was evident from these facts that the patient had an obstruction somewhere in her abdomen; but because of the patient's resistiveness, the location could not be determined. She refused operation at this time, also further examinations. Her condition gradually grew worse until she could retain nothing given by mouth, not even liquids.

On December 26, 1921, she began showing definite evidence of acidosis with marked acetonuria and a distinct acetone odor to the breath. Everything by mouth was discontinued, and for several days ten per cent. glucose and five per cent. soda bicarbonate enteroclysis was given against the patient's will, but was poorly retained. For the first time since her admission she began to complain of intense colicky pains in the upper abdomen. These attacks were frequent and required morphine for their relief. The severity of these attacks and the gravity of her condition seemed to change her attitude, so that she seemed willing now to cooperate a little with us in further treatments. The vomiting still continued as before, the vomitus being of the same character as previously noted.

On December 30th, the patient made a confession to me in which she stated that a week or so before her admission to the hospital (which would be about November 18th) she had swallowed two paper packages of pins with suicidal intent, as she had been considerably depressed over her inability to work and on account of the hemiplegia. Asked how she was able to swallow these, she replied that she had taken them enclosed in fruits such as bananas or apples. She stated that she had been once told by a nurse that this was the easiest method of committing suicide. Shortly after taking the pins, she took some citrate of magnesia as a laxative, and since then had had attacks of abdominal pains off and on, which, during the past week or so, had seemed more severe. On December 31st, a rectal examination was done. It revealed marked impaction of feces, and on breaking up the impaction, a pin was felt and extracted. The bowels moved well after this, the stools containing many blood clots and shreds of tissue. On account of the acidosis 200 c. c. of a ten per cent. glucose and five per cent. soda bicarbonate solution was given intravenously with good reaction on the part of the patient. This was repeated every twelve hours for five days, at the end of which time the acetone odor to the breath had disappeared and there was no longer any acetonuria. During the administration, ofttimes the patient would show signs of tetany which ceased after administration. On January 2d another rectal examination showed another fecal impaction and six more pins were extracted. During the night the patient

vomited some watery material, in which was found two pins. The general condition of the patient at this time was much improved. She did not vomit nearly as often as previously and except for severe abdominal pains requiring morphine at times, no other symptoms were complained of. On examination of the abdomen a fairly large tender mass was felt in the right hypochondrium, the mass being indefinitely made out became of the tenderness. Another smaller mass was felt in the left hypochondrium and it, too, was tender. In fact there was tenderness over the whole abdomen, more marked in the right quadrant. An abdominal x ray taken at this time showed a large mass containing projecting pins and present on the right side, as in the accompanying plate.

On January 6th, the patient's condition having been sufficiently improved to warrant it, it was decided as the only possible means of saving her life, that an operation should be performed, with the patient's consent, which was accordingly done.

A medium incision was made and the peritoneum opened. A small amount of bloody fluid was present in the peritoneal cavity. The cecum was found filled with gas but no obstruction was found either at the ileocecal junction or at any part of the large intestine. The small intestines were collapsed and presented a peculiar appearance—one loop of bowel had a normal pinkish color whereas the next loop was cyanotic, this alternation of colors being present throughout the entire small intestine. No obstruction was found anywhere in the small intestine. A large mass was found present in the right hypochondrium in the cardiac end of the stomach. The stomach was contracted and on its anterior surface near the pylorus there was a large perforation covered by plastic exudate. A fairly large transverse incision was made in the stomach and the contents inspected. The latter was very bloody and the mucosa injected. A large mass of pins forming almost a complete cast of the stomach was removed in several pieces. One of the largest portions is shown in the accompanying photograph (Fig. 1). The mass contained several hundred pins, all intermeshed with blood clot. After cleaning out the stomach as much as possible, the incision was closed with catgut and silk. The perforation was closed with difficulty, the stomach wall being too friable. The abdominal incision was then closed in the usual way.

The pulse at the end of the operation was rapid and weak, and the patient in a condition of marked shock. She reacted slightly after intravenous saline and partially regained consciousness. Her condition grew worse shortly afterward and another intravenous saline produced temporary improvement. Death occurred the next morning at 8.45 a. m. from shock and acute cardiac dilatation. Permission for an autopsy was not obtained.

Several factors make this case interesting and instructive. 1, The large number and unusual character of the foreign bodies swallowed, also the unique manner in which this was done. Although it was not possible to determine the exact number of pins ingested, if we take the patient's statement as valid, she must have swallowed five hundred straight pins, the number contained in two packages in addition to eight or ten safety pins. This is a large number, although in several reported cases more have been removed at operation. Probably the largest number recorded in the literature was reported by Winslow (5) in August, 1918. He removed from the stomach of an insane man 1290 different objects, consisting chiefly of straight pins. Winslow's case resembles in many respects the case herein reported, but is more unusual than that in spite of the large number of foreign bodies present, and the fact that they had been present about two years, yet the patient made a complete postoperative recovery.

2. The danger of this type of foreign body to the patient's health. It causes marked changes in the stomach wall with thickening friability and, as in this case, perforation and local peritonitis, rendering satisfactory operation difficult. If allowed to go on without operation, death is inevitable either from starvation and acidosis or from septic peritonitis, the result of mechanical obstruction and perforation.

3. Nature's remarkable fight against odds. It was three weeks or more after the ingestion of the foreign bodies before the patient began to show any gastric symptoms.

4. The great value of the x ray as a diagnostic aid in these cases. Had it been possible to use it shortly after the foreign bodies had been swallowed, in all likelihood, with prompt operation the patient would have recovered.

5. The necessity for prompt operation in this type of case is emphasized. If allowed to go untreated, perforation and peritonitis result, naturally rendering operation more difficult but making for a grave prognosis.

SUMMARY

An unusual case of multiple gastric foreign bodies is reported, the foreign bodies consisting chiefly of the contents of two paper packages of pins swallowed with suicidal intent by a woman apparently insane. At operation performed seven weeks after the pins were swallowed, a large perforation of the stomach wall, with local peritonitis, was found. A mass of pins was removed from the stomach and the incision in the latter closed with difficulty. Death occurred in about fifteen hours from shock, and acute cardiac dilatation. The various types of foreign bodies are reviewed and their possible dangers to the patient's health. The necessity for early diagnosis and prompt operation is emphasized. Cases are cited from the literature to bear out these facts.

In conclusion, this case should serve as an object lesson to us in the future, so that in all obscure abdominal conditions, especially with a mass present, we should bear in mind the possibility of the presence of foreign bodies, should use the x ray early and frequently, so as to arrive at a prompt diagnosis, and finally, with early diagnosis, immediate operative intervention will give the patient the best possible chance for recovery.

Factors Resulting in the Lowered Mortality of Prostatectomy*

HENRY BUGBEE, M.D.,
New York

It is not my desire to present to those interested in the general practice of medicine, surgery and the various specialties, a technical paper dealing with details of surgical technic or an argument for one type of procedure in the handling of the prostate as superior to all others.

This work has become sufficiently standardized so that urologists are agreed upon the principles behind the general management of such cases. Each urologist should follow the technic which, without prejudice, he has found most successful in his hands and the following is a general presentation of the methods employed by me, which represent a slow process of evolution in my own practice and which have given me the best results.

The reason for this presentation is to place before you the general problem and certain phases of its solution to date.

In a paper presented before the New England Urological Society in January, 1920, I reviewed briefly the history of prostatectomy.

It is of interest in glancing over this history to note that from the discovery of the prostate by Nicolo Massa, a Venetian physician who died in 1563, and the association of the swelling of the prostate with urinary retention by Riolanus in 1649, up to the present period of enlightenment in urology, the investigators in the study of prostatic obstruction were focusing their attention upon a local bladder condition. Their efforts were directed solely to a relief of the urinary retention and the resulting mortality was high.

While the possibility of studying the obstructing lesion became possible through the introduction of modern cystoscopy, a real appreciation of not only the urological condition of the patient but its effect upon the organism as a whole was not recognized until kidney function tests became standardized.

A realization of the kidney disturbance arising from prostatic obstruction and its resulting back pressure led to a more careful study of the patient as a whole and especially of his cardiovascular system. The technic in the handling of these cases which has resulted from such study, has placed one of the most serious surgical procedures upon a solid foundation, making possible the restoration of health and function to the patient, giving years of comfort to those otherwise destined to suffering, impaired activity, and in many early death.

In dealing with a case of prostatic obstruction, an accurate diagnosis of the lesion is essential. This step must be considered as part of the preparation of the patient for operation. Preparation of the patient is the one element above all else that has resulted in the lowered mortality from prostatectomy.

Each patient from the time he first presents himself for study must be handled according to the particular indications in his case. Very seldom is it wise or possible to make a complete examination of the patient suffering from prostatic obstruction when he is first seen. The patient's history is important, a general physical examination gives a fair idea of his general physical condition, a rectal examination reveals much information regarding the prostate, but further investigation should be postponed.

Prostatic obstruction is present in men of advanced years, seventy-five per cent. in men over sixty-five years of age, in whom tissue changes have taken place (they are on the decline). The local condition has often progressed slowly, the body accommodating itself to the changes. A break in the compensation should be brought about as slowly as possible.

While we are beginning to see cases of prostatic obstruction in the earlier stages, due to education of the public, yet the majority still come with a well defined pathological lesion.

In an early case with indications of but a few ounces of residual urine, it may be safe to pass a catheter or even cystoscope the patient at once. I prefer to give a urinary antiseptic for a few days, increase the fluid intake and clear out the intestinal tract thoroughly before carrying out any intra-urethral manipulation.

If there is evidence of bladder distention it is better, if possible, to place the patient in the hospital before attempting to relieve the retention. If the retention is complete some relief must be obtained at once. Seldom is catheterization impossible if prop-

*Presented before the Medical Association of the Greater City of New York at its stated meeting, held January 21, 1924.

erly carried out. A local anesthetic reduces the hypersensitiveness of the urethral mucous membrane. Manipulations must be gentle and the proper care used in each case. Rarely a silver catheter will have to be employed and assisted in its passage by elevating the tip of the catheter by means of a finger in the rectum, lifting it over the raised floor of the prostatic urethra.

No bladder containing over six ounces of urine should be emptied at the first catheterization. The catheter should be tied in and small amounts drawn off every hour, while fluids are forced by mouth, and by rectum if necessary.

An overdistended bladder may be relieved by suprapubic puncture when, with partial relief of pressure, catheterization may be possible or suprapubic drainage may be instituted at once. If the latter is resorted to under local anesthesia the bladder should be exposed and a clamped off mushroom catheter inserted into the bladder through a small opening, the bladder not being allowed to empty itself in the process. Small amounts should be drawn off at regular intervals as in the case of an indwelling catheter.

Too much stress cannot be laid upon the importance of not completely emptying an overdistended bladder at the first sitting. The complete removal of all back pressure upon the kidneys results in congestion of the kidneys and possibly complete suppression. While a gradual relief of pressure will be accompanied in many cases by uremic symptoms, the kidneys slowly become stabilized and the patient passes through the first and what should be the most critical stage in the relief of prostatic obstruction. The majority of patients will have drainage of the bladder by means of an indwelling urethral catheter while the kidney function is being studied by means of the phenolsulphonephthalein reaction, blood chemistry and observation of the patient for the disappearance of uremic symptoms such as a dry, coated tongue, loss of appetite or even vomiting and hiccough, abdominal distention, possibly fever and disturbed mental equilibrium.

The cardiovascular system is observed and especially the blood pressure which often drops with the relief of back pressure upon the kidneys, later becoming stabilized with the like behavior of kidney function. The respiratory system is often impaired and deserves special consideration. A complete flushing of the system by means of forced fluids (especially water) and colonic irrigations is probably of greater benefit than all other measures in reestablishing the kidney and cardiac functions.

When the patient's urethra has become tolerant to the urethral catheter, the urine cleared and the kidney function improved, a cystoscopic examination should be made. A cystoscopic examination is possible in nearly every case. The often distorted, elongated posterior urethra calls for the most delicate manipulation of this instrument. By using a small cystoscope, elevating the beak, if necessary by lifting it over the edge of the prostate with a finger in the rectum, rotating the instrument rather than moving it about in the bladder, and not having the bladder fully distended while making the examination, no harm will result and little discomfort accompany the procedure.

The information gained by such an examination is invaluable. The type and extent of the intravesical protrusion of the prostate is noted; often a definite hypertrophy is found in the bladder when no enlargement was evident by rectal palpation. A seeming hypertrophy may prove to be a fibrous prostate, malignancy may be discovered or a bladder growth, calculus or diverticulum of the bladder may be found. If the obstruction proves to be one calling for a prostatectomy and the patient has become stabilized, how shall we proceed with the greatest degree of safety to the patient?

The objects of the operation are to remove the prostate completely, thus eliminating the obstruction to do this, with as little disturbance or shock to the patient as possible, and to have normal bladder function after its removal.

There are two general methods of approach in this procedure, through the perineum and suprapubically. While, in the hands of the best operators each seems to involve about the same amount of operative risk, hardly any two operators follow the same technic in all its details. The actual removal of the prostate at the proper time when the patient has become stabilized in all his body functions, safeguarding against the possible operative complications should be carried out with little shock to the patient and should be an incident in the patient's convalescence from the broken kidney compensation and the effect of such a break upon the various body functions,

The technic employed by me during the past five years, with slight modifications, has been attended by a single mortality in a series of forty-two patients operated upon during the past year, the one fatality being due to a pulmonary embolus (occurring in a patient originally a bad risk) after the wound was healed, the bladder function normal and the patient was waiting to leave the hospital.

Aside from occasional cases in which a perineal operation is particularly indicated, or a punch operation advisable, the technic briefly is as follows:

Following the partial restoration of kidney function after drainage of the bladder with the indwelling urethral catheter, suprapubic drainage is established under local anesthesia in the manner before described. An indwelling catheter causes a varying amount of local irritation in the urethra as often shown by a urethral discharge, by edema of the mucous membrane about the vesical neck and a lack of complete relief of congestion of the prostate. That drainage is not complete by means of the catheter is evidenced by the frequent return of uremic symptoms on establishing suprapubic drainage even though the kidney function had become partially restored following catheter drainage. Time is not lost by this step for the wound is allowed to heal about the suprapubic tube. The bladder is now placed at complete rest, fluids may again be forced, bladder infection rapidly subsides, the urethra is relieved of the irritation from the catheter, congestion of the prostate is diminished and when the patient assumes a thoroughly "even keel," the prostate may be removed with an assurance of little accompanying shock or systemic disturbance.

A period of from five days to several months in a few cases has been allowed to elapse before com-

pleting the operation. The average time is ten days although in patients presenting serious heart or kidney complications one should not hesitate to allow the patient to go about with the suprapubic drainage tube in position, or leave the hospital to return later for completion of the operation.

I have seldom found patients restless under this postponement when the gravity of the situation is explained to them, and the ease and comfort with which they get about as well as go through the subsequent removal of the prostate is most surprising.

When the patient is ready for the removal of the prostate this step is carried out preferably under regional anesthesia, i. e., parasacral anesthesia supplemented by infiltration of the rectus muscle about the suprapubic sinus. This anesthesia should be given by an expert. The variations in the conformation of the sacrum necessitate experience and skill in its administration. When properly administered, the anesthesia is ideal, the operation being painless and muscular relaxation complete. There is less danger of pulmonary complications; less strain on the heart and kidneys; it renders possible the continuation of nourishment without interruption, to force fluids immediately after the operation and in the cases in which it has been employed I have seen no untoward effects.

In one recent case the patient presenting severe impairment of the myocardium having been refused by several surgeons as too poor an operative risk, went through prostatectomy under sacral anesthesia with no complications. A second patient given gas oxygen anesthesia for preliminary drainage had a pulmonary embolus and thrombosis of the dorsal artery of the penis, yet two weeks later, a prostatectomy under sacral anesthesia was entirely successful. A third patient had an acute dilatation of the stomach after gas oxygen anesthesia one year ago and recently went through a bladder operation under sacral anesthesia with no complications. This method of anesthesia represents one more refinement of technic which further eliminates the possibility of complications which in old men are not infrequent following inhalation anesthesia however skillfully administered.

With the patient under the influence of regional anesthesia the suprapubic drainage tube is removed. The sinus is dilated and if necessary, in stout individuals, enlarged slightly toward the pubis. The original wound is not reopened. With a finger introduced through the sinus into the bladder and cervical neck, aided by an elevation of the prostate by means of the fingers of an assistant in the rectum, the prostate is enucleated from its capsule and removed. The difficulty of removing the prostate through a comparatively small suprapubic opening even in patients with a thick abdominal wall has been much exaggerated. I have not found it impossible in any patient operated upon, and in the majority a exceedingly simple procedure. While hemorrhage always takes place in varying degree following the enucleation of the prostate, it is decidedly less severe in cases that have had preliminary suprapubic drainage. It should always be controlled. Any loss of blood at this time lowers the patient's resistance and further interferes with kidney function. I have found the Pilcher bag satisfactory for this purpose. It is easily introduced by means of a special sound which is attached to the urethral tube, the bag is partially filled with fluid and is drawn down into the prostatic capsule. Packing loosely placed about the bag fills the prostatic cavity so that bleeding is controlled by slight traction on the urethral tube which is maintained for not more than two hours. At the end of this time the traction is removed but the bag remains in position and can again be pulled tightly into the deep urethra if bleeding recurs. This we have not found necessary. The bladder drains through the urethral tube keeping the patient dry.

The pressure of the bag and packing often causes vesical tenesmus of varying degrees. With the short period of traction now employed tenesmus is not severe and disappears at once when the bag and packing are removed the following day.

With a small suprapubic sinus and a bladder free of blood clots, it is now possible to introduce again a mushroom drainage tube into the bladder through the suprapubic sinus. The tube fills the sinus and drainage is complete at once, the patient is not wet from poor drainage and he is in the same condition as on the previous morning before the prostate was removed.

The patient is encouraged to drink large quantities of water which is also given by rectum and by hypodermoclysis if necessary, elimination being thereby assisted; he is kept in a sitting position and convalescence should be rapid. In from seven to twelve days the suprapubic tube is removed, the sinus packed to promote closure of the bladder opening first, the sinus thus closing from the bottom. An indwelling catheter is inserted into the urethra. This is retained until the suprapubic opening has closed. The average length of time for this closure is twelve to sixteen days after the removal of the prostate.

As regards morbidity, I have not had incontinence or stricture resulting in any case operated in this manner. The sexual function is not apparently impaired and in no case has it been necessary to reoperate for the enlargement of any prostatic tissue left at the original operation.

REPORT OF A CASE

I should like to cite a recent case as representing a desperate type and the minor importance of the operative phase.

CASE.—A man, seventy-six years of age, entered the hospital with complete retention. He was thought to be suffering from broken cardiac compensation, nephritis and suppression. His myocardium was weak, the heart action irregular, blood pressure 90, nutrition poor, and it was questionable whether he would survive from day to day. The prostate was enlarged, retention was relieved by urethral catheter drainage. During a period of two weeks, under general supporting measures, his condition improved sufficiently to warrant a suprapubic drainage under local anesthesia, as it was impossible to maintain satisfactorily the urethral catheter in position. A period of low ebb was maintained for the next two weeks marked by semicoma, complete loss of appetite, intestinal stasis, blood pressure of 85, weak, irregular pulse and kidney function which gave no reaction with phthalein and as high as 68 blood urea. The greatest care was given to every detail of feeding, forcing fluids, care of the bowels

and medication with little improvement. A transfusion at this stage proved to be a turning point for he at once improved so rapidly that he could be moved to a convalescent home where his bodily functions were partially restored and he returned for the removal of the prostate which was accompanied by no reaction whatever. He was out of bed the following day and the wound healed at once. He has since gained thirty-six pounds and is now engaged in active work.

Success in this case was due to attention to every little detail in its management and not to any particular operative technic. From such a case which represents the greatest surgical risk, we have cases ranging to an occasional good surgical risk. As before stated, we are seeing earlier types of obstruction which in their relief should carry no real operative risk. On the other hand, we are tackling cases so low in function that operation formerly would not have been considered. I have advised against operation in but two cases of prostatic obstruction in several years because of their being a poor operative risk. One patient who had had uremic convulsions was later operated upon by another surgeon, and never came out of the anesthetic. The second, who had diabetes of years' standing, a well as a central nerve lesion, was operated upo elsewhere and lived but a few hours after operatio

A number of urologists have reported series o well over a hundred consecutive cases of prostatec tomy without a death. Possibly these series hav contained many early cases carrying little risk, o the operators besides being skillful and thoroughl conscientious, observing every precaution for th welfare of the patient, have been fortunate as well— or after such a long string of successes, there ma have followed a group of fatalities.

If one takes the bad with the good, and no sur geon encounters greater risks in any class of surgica work than in prostatics, there must be an occasiona mortality. That the mortality resulting from thi operation has been placed below five per cent. b most urologists, reflects great credit upon the wor of those who have made such a thorough, scientifi study of this complex problem, who have applie skill and patience in its solution, each perfecting hi own technic and frequently presenting it for dis cussion, all appreciating the common basis of th general principles involved.

40 East Forty-first Street.

Chancre of the Cheek

HERMAN GOODMAN, M.D.,
New York

In general, about six to ten per cent of all known chancres are situated elsewhere than upon the genitals. A larger percentage of women than men seem to acquire the disease in this way, although it must be admitted that fewer women present a chancre, coming for consultation as they ordinarily do in the secondary generalized period of the disease. Because of the greater susceptibility of mucous membranes to chancre formation, and offering as they do, better fields for the well being of the Spirocheta pallida, the mouth next to the genitals presents the greatest number of chancres.

Parts of the head are the site of syphilitic chancre in odd proportions. As always, one must refer to Bulkley's admirable collection of figures in his monumental, *Syphilis in the Innocent* for statistics. He lists 145 cheek chancres among a total of 9,058 located extragenital chancres. He added five cases of his own, all in males.

Case I.—We present herewith the photograph of our most recent patient with chancre of the cheek. The case is worthy of reporting as the history given by the patient was unencumbered with odd details. The patient reported to the West Side Dispensary and Hospital and complained of the lesion on his cheek which had been present about two weeks. He had done nothing for it, and wondered what it was. His habits as to living were rather exemplary and he had not exposed himself to venereal infection for a long period. He said that it was his habit to shave himself at all times, except that when he visited the barber shop for a hair cut, which he did at regula intervals of four weeks, he allowed the barber t shave him. The sore had made itself evident to th patient on the occasion of his regular visit to th barber, so that there was a period of no symptoms o at least four weeks. During this interval, there wa no change in the man's manner of living, and n mode of infection other than through the mediu of the barber was apparent. As far as we coul ascertain the procedure at the barber's for shavin was what it was in all such places, but we did ge the positive statement that the barber had gone ove his face twice. It was not possible for us to ex amine the barber, so we are not in a position to stat whether the contagion was mediate, that is directl from some lesion on the attendant barber, or in er mediate, that is through the medium of one of hi utensils or towels. The reason we particularly men tioned the double use of the razor was in order t bring in the fact that Reasoner definitely showe that a solution of soap is lethal to spirochetes i dark field experiments. The fact that soap lathe was applied twice to the patient's face would indicat that the spirochetes were in all probability from th person of the barber or present on a towel or powde puff, or other utensil used after the immediate shav ing. The patient did not remember having been cu or that the barber used a styptic stick. As th patient did not expose himself to infection by sexua contact, the contention that most, if not all, infectio of this character are due to contamination after th

patron leaves the barber shop, probably does not apply in this instance.

The clinical appearance of the lesion as shown by the photograph made the diagnosis of syphilitic chancre. The diagnosis was confirmed by demonstration of the offending organisms, the Spirochetes pallida. The patient despite every assurance that he had syphilis, refused treatment, and did not return to us. However, at a meeting of the Section of Dermatology and Syphilology of the New York Academy of Medicine at a subsequent date, we saw the man again. The primary lesion was still present, and in addition, he showed typical glandular enlargement behind the ear, and a macular eruption of secondary syphilis generally distributed.

Case II.—A man of sixty years applied for treatment with a lesion on the left cheek said to have been present about ten days. He gave a history of shaving himself and that one evening after shaving with usual good results and no cuts or abrasions, he left his room to go to work as night switchman on a railroad. He passed the rooms of his landlady, who was in the midst of her washing and standing at the tubs with soiled clothes about made an agreeable picture to the patient, who in giving the salutations of the day, playfully tilted the lady under the chin. In reprisal, the lady cuffed him on the cheek, but her blow was not so playful or else the cheek was struck by her nail, for the skin was cut, and blood appeared. The landlady apologized, stooped over, picked a towel from among those about to be washed, and used the end of it to stanch the flow of blood. A crust formed, and the man left for his work. The next time he shaved, the crust was removed with the razor, and this time, he used a fresh towel to stop the bleeding. The new crust which formed was not further disturbed, but as far as the patient could determine there was no indication of any healing process. The lesion seemed to be getting worse instead of better.

Numerous and varied were the clinical suggestions made at the time of examination at the hospital, among them: syphilis, either primary, or tertiary; tuberculosis; epithelioma; infection. Unfortunately, no dark field apparatus was available at the time so spirochetes were not searched for; blood for a Wassermann test was taken and subsequently reported negative, and mild wet dressings were advised. The patient did not return to us immediately, but we learned that he had become a patient at another clinic, where the official diagnosis was, infection, with non-virulent pus organisms. Some time later, the dermatological division of the hospital was invited to see a patient on the surgical side who had been prepared for operation for a huge carcinoma of the face, and who in addition presented a generalized eruption which required diagnosis. With other members of the staff, I saw the patient, and he presented a giant ulceration of the chancre site, and a remarkable pustular secondary eruption of syphilis. The Wassermann was reported four plus positive; treatment removed the clinical evidence of the disease, but as I remember the history of the case, the serology persisted positive up to the time I lost sight of the patient.

Case III.—We have records of another case of chancre of the cheek, although it is only a history. A young lady presented herself with a tertiary ulcerative syphiloderm of the forehead. As she was only nineteen years of age, we were hard put to determine when she could have been infected as there were no stigmata of congenital syphilis present. On questioning, we learned from the mother, that when the patient was an infant, her uncle, who knew himself

Fig. 1.—Syphilitic chancre of the cheek.

Fig. 2.—Chancre probably acquired in barber shop.

to be infected with syphilis, kissed his niece on the cheek apparently in a vain attempt to prevent inoculating her on the lips. A sore followed which took some time to heal, and the attending physician ordered precautions and treatment as for syphilis. Unfortunately, the treatment was not sufficient to entirely rid the young patient of her disease, and at nineteen, she presented the late manifestation mentioned above.

Efforts to diminish infection through the barber shops have been initiated in many communities by regulation and supervision of the trade. The larger cities have introduced many requirements for sterilization or near sterilization of instruments; have eliminated the use of the common powder puff; insisted on a freshly sterilized brush for each patron; the use of towels only on one customer; abolished the common shaving mug, and piece of soap. These reforms are excellent. However, so much depends on the barber's conscience that the best rules and regulations may all go for naught. Indeed, recently, we have seen a young boy, who undoubtedly acquired a syphilitic infection in a modern, supposedly regulated barber shop, through the definite medium of the barber being so good hearted as to promise to abolish, what he called, an ingrown hair. The barber used a pair of forceps, taken from a drawer or cabinet, made no effort to even cleanse this instrument, toiled around the site of the offending spot, and infected it with syphilis. When the boy reported to us, he presented a chancre on the side of the neck, and marked secondary skin manifestations of syphilis. The report of this case and the photograph are given through the courtesy of Dr. Williams.

Despite opinions of others that chancres of the cephalic region evidence greater tendency toward severe secondary syphilis, and involvement of the central nervous system, our experience with this location of chancre has not tended in this direction. Of course, the possibilities are always greater that the chancre is not recognized as early when located on other parts than the genitals, and in this way the

future of the patient may be endangered by delayed treatment or no treatment at all.

The prophylaxis of extragenital chancre and hence, syphilis, is a social problem. As far as the barber is concerned, it is logical that he ought not be allowed to practise more than barbering; and the wise patron will insist that once over be the limit in the public barber shop, to avoid the possibility of extra trauma on a skin already devoid of perhaps its greatest protection against infection, an unbroken skin, and a keratin layer.

15 Central Park West.

Prostatic Obstruction*

JOHN A. HAWKINS, M.D.,
Pittsburgh, Pa.

The interesting subject of prostatic obstruction, replete with its massive collection of historical data, can only be touched upon in a paper of this kind. However, referring to Walsham (1) we read: "Hypertrophy or chronic enlargement of the prostate must be distinguished from enlargement due to inflammation. It seldom occurs under the age of fifty or sixty. It may be due to hypertrophy of all the tissues forming the prostate, or the glandular, muscular or fibrous tissue only. The enlargement may involve the whole prostate or may be confined to one or other of the lateral lobes or to the socalled middle lobe. The causes are unknown." Thirty-six years later no better definition can be given and we are as much in the dark as to its causes.

The inflammatory obstruction will be briefly considered later and malignancy will be mentioned. For the present we will consider senile prostates only. John Hunter 165 years ago ascribed the cause to inflammation. Inflammation in those days was a broader term than now; yet, little has been proved to controvert Hunter.

Prior to 1888 a number of methods were devised to do away with the constant use of the catheter. We find that suprapubic aspiration had been used; perineal section and draining; removal of a portion with the prostatectome—a punch described in 1892 (2); or with Jessop's prostatic scissors, similar to the well known tonsil guillotine, as well as many other schemes.

In 1893 J. William White (3) reported the beneficial results he had secured by double castration, and the same year Bier reported cures after ligating one or both internal iliac arteries. Cures were reported by others by both methods, as well as by vasectomy which was very popular with some English surgeons.

During this period others were thinking seriously of attacking the prostate directly. Schmidt, Guyon, McGill and Belfield evidently had performed prostatectomy prior to 1893, for Fenwick calls attention to failures due to leaving portions of socalled suburethral growths. At this time Belfield wrote that the object is to secure a "low level outlet through the prostate and is not simply excision of the overgrowth." The fact is that both Belfield's and McGill's work dates back to about 1888.

Pyle (4) more than thirty-one years ago described the operation of perineal prostatectomy by a curved incision in front of the anus, separating by blunt dissection between the bulb and the rectum, using volcellum forceps to remove the lobes, and a curved steel sound to steady the base of the bladder. This operation on a seventy year old patient was successful.

Removal of a part of the obstruction by the galvanocautery had been used in those early days, and like the punch operation was resurrected later.

In 1887, McGill of Leeds reported four operations. Two years later twenty-four operations were reported. In these, four patients died; seven no longer required the catheter, and thirteen were not improved. Not encouraging! At that time the hypertrophy was removed by a cutting instrument the pieces varying from that of a pea to a filbert or slightly larger. In McGill's twentieth case he cut off the middle lobe with forceps and removed the lateral lobes with his finger. This same procedure had been used shortly before by Atkinson. These were all transvesical operations.

In addition to chronic obstruction due to hypertrophy, to contraction of the vesical neck by the fibrous prostate, and to malignancy, obstruction may be due to acute inflammation of the prostate.

Many patients report that they have been free from all symptoms until they suddenly discover their inability to void. This disability usually occurs at night. These patients should not be urged to immediate operation. They should be given a hot bath, put to bed, and a soft rubber catheter tied in for twenty-four or thirty-six hours. After removal the patient may be able to void within a few hours. If not, repeat the procedure for the same period. I have seen patients go about for months and even years without operation. Recently a man of fifty complained that for eight hours he had been trying unsuccessfully to void. He was catheterized once since which he has continued to void. He has from one to three ounces of residual urine. It might be stated that this expectant treatment is particularly indicated in those cases where the prostatic enlargement is not dependent upon an actual overproduction of the interstitial fibromuscular tissue, or even overproduction of glandular elements, but rather is dependent upon some transient process, as, for example, an increased blood content resulting from an inflammatory process; or the type of cystic process in which the alveoli are widely dilated and distended with secretion. It is in the latter types of cases that the expectant treatment described reduces the gland to the point where urination is practically normal

*Read at a meeting of the Allegheny County Medical Society, Pittsburgh, Pa., December 18, 1923.

Cases which do not yield to treatment within a reasonable time must be dependent upon an absolute increase in either interstitial or glandular elements and justify operative interference.

The hard fibrous prostate, which may completely surround the vesical neck, thus forming a rigid ring or collar, is frequently, if not always, malignant. At least it is very common for malignancy to start up in or near the former site of the prostate. Therefore a guarded prognosis should be given at the time of operation.

The adenomatous growth, which is most often found, varies in size from an English walnut to a large apple or larger and may be present for years without causing severe symptoms. Retention sends the patient for relief. Do not mistake a urethral stricture, stone or the retention of tabes for retention due to the prostate; but all may coexist in the same patient. Although I have mentioned that the symptoms may occur suddenly, yet patients usually are troubled for a varying length of time by frequency, particularly nocturnal, small stream, difficult to pass, followed in time by dribbling and retention. A patient's bladder may become so distended that it overflows. Long continued back pressure produces irreparable damage. The bladder walls become thin and their musculature separated forming exaggerated trabeculation; the ureters and renal pelves, and even the kidneys themselves dilate, the latter becoming hydronephrotic and later pyonephrotic. The patient is then a decidedly poor surgical risk.

Rectal examination may give the impression of an enormous prostate, which disappears after fractional catheterization has been completed. Moreover, large prostates felt rectally are not the ones that produce urinary symptoms; a middle lobe the size of a hazel nut will produce complete obstruction and cannot be felt by the rectum.

The average urethra is about eight and a half inches long; when longer it should be regarded as suspicious. This together with the presence of residual urine and the history in a man over fifty is sufficient to indicate a cystoscopy, which, if possible, will enable one to make a diagnosis.

The treatment resolves itself into that of operable and inoperable cases; and again for the operable cases into preoperative, operative and postoperative treatment. The patients in the inoperable group may be made fairly comfortable by drainage and attention to their general health.

A patient who can be catheterized with a soft rubber or a web catheter, needs no preliminary operation. We frequently have patients wear an indwelling catheter several weeks or a month; and one of our patients wore a catheter for three months. Epididymitis occasionally occurs. We care for both the patient and the catheter. The catheter is left in several days, removed, the urethra irrigated with one half of one per cent. solution of liquor cresolis compositus, and the urethra allowed to rest until the time for the next catheterization. It is then reinserted and this method continued until ready for operation or in an inoperable case indefinitely. Should it be impossible to insert a soft or semisoft catheter and the patient require drainage, then under local anesthesia a small suprapubic incision must be made and a drain inserted. This was the original surgical procedure for the relief of prostatic obstruction.

A patient who has been using a catheter for years seldom requires extended preliminary treatment. He has acquired a tolerance which makes him a safe risk. Recently I operated upon two patients of this class each well above eighty, on the day following their admission, and both made good recoveries. To have done a two stage operation in either case would have been needless surgery. In Young's series of 1,049 cases only eleven or one per cent. required preliminary drainage and 462 of the patients were operated within four days after admission. Moreover, there is a mortality of from two to three per cent. in the two stage operation, and in cases where I found it necessary to do the preliminary section it was slower and much more difficult due to distortion of the parts.

In addition to catheter drainage, the patient should be saturated with fluids. In order that he may get water we order eight ounces of water every three or four hours containing hexamethylenamine and benzoic acid or even a placebo, in addition to tea, coffee and milk. In some cases several litres of Fischer's solution are given by the Murphy method. This is routine postoperative treatment.

Elimination by bowel and skin is encouraged, proper diet secured, and blood chemistry and uranalyses studied. We do not attach so much importance to the phenolsulphonephthalein test as formerly. Some of the most satisfactory results occur where lowest outputs were shown. The patient's general condition is the best indicator. With a clear intellect, moist uncoated tongue, a good appetite, no headache, little or no elevation of temperature, a good blood pressure and a healthy action of skin and kidneys, a favorable result may be expected.

Long continued retention with infrequent catheterization is followed by the symptoms produced by back pressure; e. g., dry tongue, loss of appetite, headache, and dullness of intellect; all point to faulty elimination; and blood chemistry and uranalysis together with the microscope and sphygmomanometer will show a nephritis. During one winter I turned away as inoperable three of such patients. One subsequently was operated upon by another surgeon and promptly died. The other two died at their homes in peace within three months. Years ago I witnessed an autopsy in a similar case and my mortality record has been lower since then.

I prefer local anesthetics up to the point of enucleation and in old patients this is the rule. It takes more time than gas but is best for the aged. I have even began enucleation before beginning gas, with very little complaint. After the bladder is opened a little gas or gas and ether will greatly facilitate enucleation by relaxing the abdominal walls. If the patient is nervous or even anxious I think general anesthesia should be used. I am quite through with spinal anesthesia, and although I have seen sacral anesthesia used I have had no personal experience with it.

As to choice of route, I think this depends largely on who is the operator and his idea as to what constitutes a good result. I did only perineal sections up to 1913. My first operation was performed January

22, 1908, on a man seventy-seven years old with a history dating back nine years. The perineal wound closed completely in fourteen days. In twenty-four days he left the hospital but with a resolving epididymitis. He had complete control of urination. In the summer of 1913 I did my first suprapubic prostatectomy, the reason for the change being numerous epididymites, one rectal fistula, and a perineal fistula of long standing. Young admits epididymitis in twenty per cent. of his series of cases. With the suprapubic operation epididymitis is rare as is fistula, although at the present time I have a patient with a pin point fistula which I expect will close up at any time. My choice is the suprapubic operation and I believe that any prostate can be removed by that route better than the perineal one will permit. At the same time one has the advantage of being able to see the site of the operation and to explore the floor of the bladder with the eye, using an ordinary Cusco or Collin vaginal speculum. There is no danger of urethral fistula or a tear into the rectum during the suprapubic operation.

In my opinion the preoperative and postoperative treatment of the prostatic patient is far more important than the operation. A skilful operator may lose his patient by lack of preoperative or postoperative care, or judgment. Outside of hemorrhage I know of nothing that will put a postoperative patient into shock more quickly than profuse perspiration. The perspiring patient is given at once one seventy-fifth or one fiftieth grain of atropine and this is ordered to be repeated in an hour if excessive perspiration continues. The second dose is rarely needed. A Murphy drip is awaiting his return from the operating room; and he is given water just as soon as he is able to swallow. Vomiting is no contraindication to its use. In all our patients we place a one inch tube in the bladder, and recently we have not been draining into a bottle but into the dressings; this we find permits clots to escape freely with less seepage around the tube. This large tube is removed the third or fourth day; but should the tube work itself out of the wound before its intended removal, it is not reinserted. The neighborhood of the wound is kept freely covered with boric acid at all times. This prevents much of the skin irritation formerly seen. No grease is used. The two silk worm gut sutures are removed about the ninth day. The patient is propped up on the second or third day and put in a chair about the fourth day if possible. The diet is regulated as for other surgical cases. The bowels are moved by castor oil about the third day. Care must be taken with enemas and none but a soft tube should be used. It must be borne in mind that old men bear narcotics poorly and should not be given except for extreme restlessness, and then codeine should be tried first. The wound usually closes by the end of the second week.

The results secured from operations on patients able to stand the operation are usually good, the urinary control being satisfactory. But the age and frequent low vitality of these old men makes them susceptible to pneumonia, pulmonary edema, cardiac embarrassment and embolism. I do not recall secondary hemorrhages or in fact any hemorrhage following the operation that atropine did not control, except in one instance; I lost one patient from hemorrhage some years ago when continuous irrigation was the fad. I suppose I got outside the prostatic capsule during the operation and failed to use a tampon in time. Very little bleeding occurs if one keeps inside the capsule.

Bladder Disturbances of Nerve Lesion Origin

Their Nature and Management

MEREDITH F. CAMPBELL, M.D.,
New York
Assistant Visiting Urological Surgeon, New York City Cancer Institute

Disturbances of the urinary bladder are common, occurring at any age in either sex. The three most frequent causes are infection, obstruction, and nervous disorders—either functional or organic. We are here concerned with organic neuropathies; with infection and obstruction only as they may be concomitant factors. The mortality is high. This lends import to the condition. Those unfortunates suffering from bladder symptoms secondary to nerve lesions usually seek aid of the general practitioner or urologist first. Too often the neurologist and his function is overlooked unless some clinical manifestation such as tabetic gait is grossly evident. To perform properly our function as urologists in the treatment of these vesical upsets, the neurologist must be consulted. If we fail to gain this mutual cooperation when relief, comfort, improvement, and —on occasion—care may be afforded the patient, we fail in our obligation. By proper management much good can be done.

To understand better the manifold possibilities for abnormal vesical function on a neuropathic basis, let us briefly consider the nervous mechanism of the bladder. Langley and Anderson have shown that the bladder (rabbits, dogs, cats) receives motor fibres from, a, second to fifth lumbar nerves reaching the bladder in turn through the sympathetic chain, inferior mesenteric ganglion, and hypogastric nerves and plexus, stimulation of which fibres cause feeble contractions, followed by inhibition; b, nervi erigentes and hypogastric plexus from second and third sacral nerves, stimulation of which will empty the

bladder; c, fibres pass to periurethral musculature from the sciatic plexus through the pudic nerve. Thus the principal fibres emanate from the sacral cord. The spinal sensory nerves are found in the posterior roots of the first to fourth sacrals, especially second and third.

The urinary act in man (Redfisch) occurs thus: A small vesical urinary accumulation causes stimulation of bladder sensory nerve endings and produces a reflex internal sphincter contraction. A greater accumulation sets up mild reflex contractions of the bladder musculature (detrussor). It is by the spreading upward from the lower to higher centres that these additional stimuli occasion the conscious desire to urinate. In adults urination is an habitual voluntary act consisting of, a, tonus inhibition in lumbar cord thereby relaxing—inhibiting—the internal sphincter contraction; b, emptying of bladder by reflex and voluntary detrussor contraction plus aid by voluntary abdominal muscles. The external sphincter plays a small rôle, being a reserve urethral closure mechanism. Thus, with the extensive intricate and delicate nervous apparatus controlling the bladder with its many easily vulnerable points, we readily understand how a comparatively small lesion, central or peripheral, may bring about impaired function. The difficulty of correct interpretation of the clinical picture presented is manifest.

Neuropathic vesical disturbances fall into three general classes, depending on whether they are due to, a, irritation; b, sphincter spasm, or c, sphincter relaxation (paralysis). During the course of a disease, the three conditions may be observed in this order, paralysis being the status terminus. The earliest manifestations of organic nerve disease (e. g., tabes, syringomyelia, multiple sclerosis) may be vesical. Bladder neck hyperesthesia is present. The readily recognized symptoms, namely, hesitancy, frequency, or terminal dribbling, succeed.

Reflexly, the socalled irritable bladder is produced. There is variable bladder neck hyperirritability. The sources of peripheral irritation are well nigh legion, phimosis, smegma collections, balanoposthitis, venereal warts, preputial adhesions, urethral strictures, polyps and adenomata, chronic prostatitis, posterior urethritis (in the pars prostatica there are many highly sensitive terminal filaments), vulvitis, pruritis, vaginismus, labial tumors, inflammation of Skene's ducts, tumors of uterus or cervix, pericystitis, excessive coitus, renal and ureteral lesions, anal fistulæ, rectal new growths, helminthiasis, and other conditions. Any of these may produce reflex irritation and must be borne in mind in the management of all forms of neuropathic bladder disturbances.

Sphincter spasm (external) is not common in the earlier forms of cord disease and when marked, complete retention with incontinence of overflow ensues. If moderate, there is partial retention with back pressure causing fine bladder trabeculation.

Paralysis of the internal sphincter varying from a mild relaxation to total paresis is seen in such conditions as late tabes, syringomyelia, multiple sclerosis or transverse myelitis (lumbosacral). If there is disjunction of the lower from the higher centres as in traumatic transverse myelitis above the lumbar segments the socalled automatic bladder obtains. The stimulus of increasing distention reflexly produces detrussor contraction with practically complete emptying.

Neurological syndromes in which bladder disturbances are a common accompaniment are: cerebrospinal syphilis either congenital or acquired, usually in the form of tabes; cord tumors, status postapoplecticus, exophthalmic goitre, paralysis agitans, multiple and transverse myelitis, syringomyelia, tuberculous meningitis, the toxic neuritides (scarlatina, typhoid, diphtheria, lead, alcohol, etc.), and spina bifida. The last named condition must always be

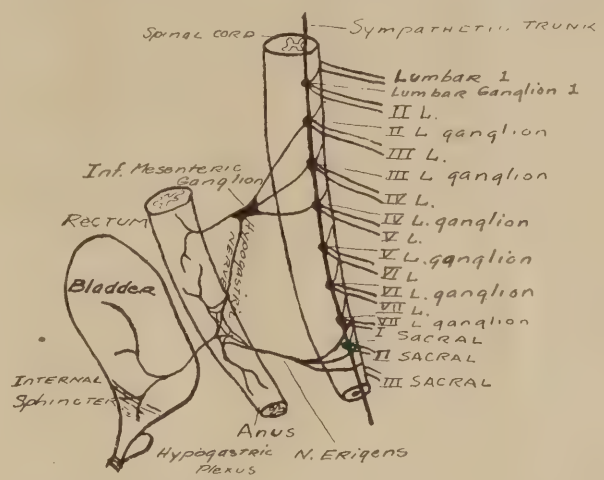

Fig. 1.—Schema of bladder and rectal innervation (*after Frankl-Hochwart and Fröhlich*).

considered especially when the etiology of abnormal vesical function seems underminable. Urinary incontinence may follow too prolonged use of the indwelling catheter.

Correct diagnosis rests upon accurate knowledge of disease. Space permits no detailed description of these various neuropathies we may be dealing with while directing our attention to an abnormally functioning bladder. Many of these disease processes are well known generally. In all except the various forms of peripheral neuritis, the posterior cord tracts are involved. In posterior tract disease, bladder disturbances are likely to be the rule. The urinary symptoms are essentially the same. We will first mention the less frequently observed lesions, and then consider in greater detail tabes dorsalis. Tabetic vesical manifestations are typical of and are commonly observed in this group of nervous diseases.

Tumors of the spinal cord, its membranes, cauda equina, and conus medullaris are occasionally encountered. Diagnosis in the presence of constant and severe root pains with associated progressive paralysis and localizing symptoms is not difficult.

Syringomyelia is due to a gliomatous new growth about the central canal of the spinal cord with cavity formation. Although bladder symptoms are not the rule, vesical analgesia, transitory sensory and motor—either irritative or paralytic—disturbances occur. A combination of an amyotrophic paralysis with retention of tactile and loss of thermic and pain sensation is said to be pathognomonic.

In transverse myelitis (compression or inflammatory), if the lumbar cord is involved vesical symptoms are present from the outset, the urine is alkaline and rapidly becomes ammoniacal. The con-

comitant cystitis is thought by some to be due to disturbed trophic influence. Myelitis in the thoracic region produces variable reflex functions. Reflexes below the lesion may be first abolished, then become exaggerated—even to spasticity. They may, however, become entirely lost.

Multiple sclerosis is characterized by localized areas in brain or cord in which the nerve elements are more or less replaced by glia tissue. The cause is unknown. Familial tendencies are noted. Several outstanding symptoms direct diagnosis. Volitional tremor, scanning speech, and nystagmus are the diagnostic triad. Spastic weakness of the legs, varying degrees of optic atrophy, the presence of the plantar reflex (Babinski), and absent abdominal reflexes are also to be noted. Bladder symptoms are present in seventy-five to eighty per cent. of these patients.

With tuberculous meningitis, bladder disturbances are not infrequent. Moreover, the appearance of acute urinary retention in a patient ill of tuberculosis is an early forecast of meningeal involvement.

The toxic neuritides, whether due to lead poisoning, alcohol, typhoid fever, diphtheria, or exophthalmic goitre may cause bladder disturbances without cord involvement. In severe cases, the wrist and foot drop, congestion of hands and feet with paralysis of the extremities and sphincters are characteristic. The symptomatology varies directly with the acuteness of the disease. The steppage gait is noteworthy.

Ninety per cent. of spinal cord diseases have their origin in lues. Syphilis in the form of gumma or pachymeningitis may produce bladder disturbances. In the form of tabes dorsalis, however, it is most potent. The mutual relation between tabes and urinary disturbances (with subsequent infection) may be realized when we consider that three fourths of tabetics have bladder symptoms (Erb). In one fourth, these are the initial symptoms. Only shooting pains are of greater primary incidence. Autopsy shows two thirds die of secondary urinary tract infection.

The diagnosis of tabes is usually easy. Certain pathognomonic symptoms are the rule. These are: the distinctive lightning pains, the loss of knee jerks and, what is equally or even more frequent, loss of the ankle jerk (Achilles), various ocular palsies, the Argyll Robertson pupil, the Romberg sign, and the characteristic ataxic gait. As previously stated, vesical upsets rank second in frequency of initial symptoms. Urinary leakage on coughing, sneezing, or sudden muscular effort may be the first symptom. Hesitancy or terminal dribbling may also appear early. There is early hyperesthesia of the vesical neck with a succeeding spasm of the external sphincter and a variable degree of retention, partial or complete. Paralysis of the internal sphincter is the end result. With this is associated bladder muscle fibre degeneration producing atony, residuum, and intermittent or continuous dribbling. The nature and course of the early symptomatology may be described as patchy. A characteristic intermittency and variability prevails. On inspection the genitals are likely to be atonic. Palpation reveals an atonic rectal sphincter. The rectum is flabby and ballooned.

Cystoscopy may be performed with impunity as a rule. An anesthetic bladder neck and relaxed internal sphincter afford a painless operation. The trigone lacks the normal firmness and appears flattened. A fine generalized trabeculation is common. It is most extensive, however, over the lateral walls and fundus. Cystitis may be marked. The ureter mouths are atonic, gape more or less, and are indurated proportional to the cystitis or ureteritis. Ureteral reflux with renal back pressure obtains. Such a lesion is demonstrated radiologically in the accompanying cystoureterogram of a case of rather late tabes which came under our care.

Bladder crises are rare. They are closely simulated by vesical stone. Especially so when the patient is suffering an acute attack of socalled "fit-of-the-stone." Illdefined contracted vesical neck, determined only by actual finger palpation, may cause symptoms in no wise different from those of advanced nerve lesion. Other obstructive lesions as hypertrophied prostate or urethral stricture must be ruled out. Hereditary or unrecognized syphilis must be borne in mind.

The prognosis of this group of cases is uncertain. It is always grave when urinary symptoms and infection appear early in the disease. The patient quickly dies of cystitis and pyelonephritis. Thus intercurrent infections, usually pulmonary or urinary, or both, kill the patient. The mortality from urinary infections is high (tabes sixty per cent.).

The diagnosis made, management and treatment become at once our problem. The objectives are, 1, to obtain and inspire confidence; 2, to keep the bladder clean, i. e., postpone infection; 3, reduce infection and residuum; 4, to relieve symptoms and if necessary, 5, to reeducate the urinary mechanism. The course of treatment herewith outlined applies to cord lesion cases, tabes especially. The peripheral neuritides are treated in like manner but are likely to be more or less transitory.

The acquisition and inspiration of confidence is naturally best performed by individual methods.

When the patient is first seen, the condition diagnosed, and the urine examined, even in the absence of infection, it is well to begin at once the administration of a urinary antiseptic. Urotropin ten to fifteen grains three times a day is perhaps the best. After twenty-four to forty-eight hours, the patient empties the bladder, a catheter is passed, and the residuum determined. Asepsis is imperative! Infection is especially easy because of trophic disturbances. About half of these bladders are infected. A residuum is found in three fourths and is often present before symptoms set in. If less than three ounces, catheterization twice a week will suffice; if under five ounces, every two days; if more, every day. At the end of catheterization, lavage the bladder with silver nitrate 1:5,000. It is well also to leave half an ounce of twenty per cent. argyrol in the bladder. The inorganic salt, however, displays a certain tonic action and hence is of greater value than the organic preparations. By this course of catheterizations the residuum is steadily reduced. This is brought about by affording the detrussor temporary relief from the strain of a urinary collection. In the absence of infection but presence of residuum urotropin must be administered, twenty gr. a day. In the presence of infection, it must be given

without remission (except for grave contraindications), forty to fifty gr. a day. Urotropin is of value only in conditions in which there is urinary retention and stagnation, whether in the bladder or in a hydronephrosis.

A periodical examination of the urine is of utmost importance and value. It is well said that the reaction of the urine (tabes) is of greater import than the Wassermann reaction of the blood. Copious fluid intake, a minimum of 2,500 c. c. a day is advised. With this quantity it is not difficult for the patient to urinate every two hours regularly during waking hours. This forms an essential habit. Under no condition should the bladder become overdistended.

Any remaining sphincter tone may be stimulated and encouraged by mild dilatation (Kollman instrument). Spasm of the external sphincter is best relieved by the cold sound. If marked, atropine is indicated.

As previously remarked sources of irritation producing disturbances reflexly should be eliminated. This entails a complete urological investigation including cystoscopy and rectal examination. A small meatus, urethral stricture or chronic prostatitis should be eradicated.

While the infection is being combated and residuum reduced, reeducation of the bladder mechanism is instituted. Much has been accomplished in the restoration of coordination, especially of the extremities (tabes) and much hope may be offered the patient with an incoordinating bladder. Degenerated nerves can not be restored but the patient is taught to utilize the imperfect mechanism remaining and to put into operation a new mechanism of nerves and muscles to replace those functionally lost to him.

This reduction is that practised by prostatic patients to regain use and control of their bladder sphincters after prostatectomy. The bladder is filled. The patient is ordered to void. Suddenly he is told to stop. The first few attempts seem hopeless. Gradually the exercise becomes fruitful. Eventually he is able to start and stop his stream at will. He must practise it at each voiding. As a rule, it is not long before he can repeat the Coué formula with truth. Such improvement inspires confidence. The frequent voidings (every two hours) eliminate much infectious material.

When lues is the underlying cause, the recognized therapeutic measures, arsphenamine, neoarsphenamine, silver arsphenamine are efficacious. Much care should be exercised, however, that treatment in late syphilis be not too intense as compared with that of early syphilis. Apparently much may be offered those suffering with late syphilitic manifestations by tryparsamide treatment as shown by the recent work of the University of Wisconsin investigators (Loevenhart, Lorenz, Bleckwenn, Hodges). Mercurialized serum intraspinally has given excellent results

With nicest attention to detail, we may offer invaluable aid to those suffering from a long lingering disease entailing much misery and a high mortality. Many can be restored to a livable and useful life.

17 East Forty-second Street.

Stricture of the Ureter*

N. P. RATHBUN, M.D.,
Brooklyn

Stricture of the ureter occurs frequently, as is evidenced by the fact that in my clinic at the Brooklyn Hospital my associates and I diagnosed and treated ten cases in August, eight cases in September, and five cases during the first three weeks of October, at which time this paper was completed. This would indicate an average of about one hundred cases annually, which I believe is a fair estimate of the number of these cases seen in our clinic during the past two years. I am confident this number will increase now that we are looking for them more carefully. Of these twenty-three cases sixteen were in males and seven in females.

This condition presents a fairly definite clinical picture; it is readily diagnosed if one but has it in mind, and it is easily relieved by simple manipulations which can be carried on in the office. And yet in proportion to its incidence it is rarely diagnosed and what is of greater importance, it is often mistaken for other pathological conditions, as a result of which patients are subjected to entirely needless and useless operations. I would hazard the opinion that each of us could readily recall one or more patients who have had appendix or gallbladder or tubes or ovaries removed, with no relief from their symptoms. I would further venture the opinion that many of these victims had stricture of the ureter.

The entire credit for bringing this matter to the attention of the profession is due to Hunner of Baltimore. In 1915 he read a paper before the Genitourinary Section of the New York Academy of Medicine which in my opinion marked an epoch in the progress of urology. In this paper he maintained that such a condition occasionally occurred as a primary urological lesion, and that if one had it in mind it could be readily diagnosed and treated. This paper had rather a cold reception and all of the discussion was entirely adverse.

Stricture of the ureter as a complication of tuberculosis, malignancy, or lithiasis had long been recognized, but there it was only an incident in the course of the major lesion. It was difficult to conceive of such a lesion existing *per se*. Not at all discouraged by criticism and doubt of the merit of his contribution he persisted in his investigations and continued to read and publish papers reporting his progress. In the spring of this year (1923) he read another paper at the New York Academy of Medicine in

*Read before the Medical Society of the County of Kings, November 20, 1923 (*From the Urological Service, Brooklyn Hospital*).

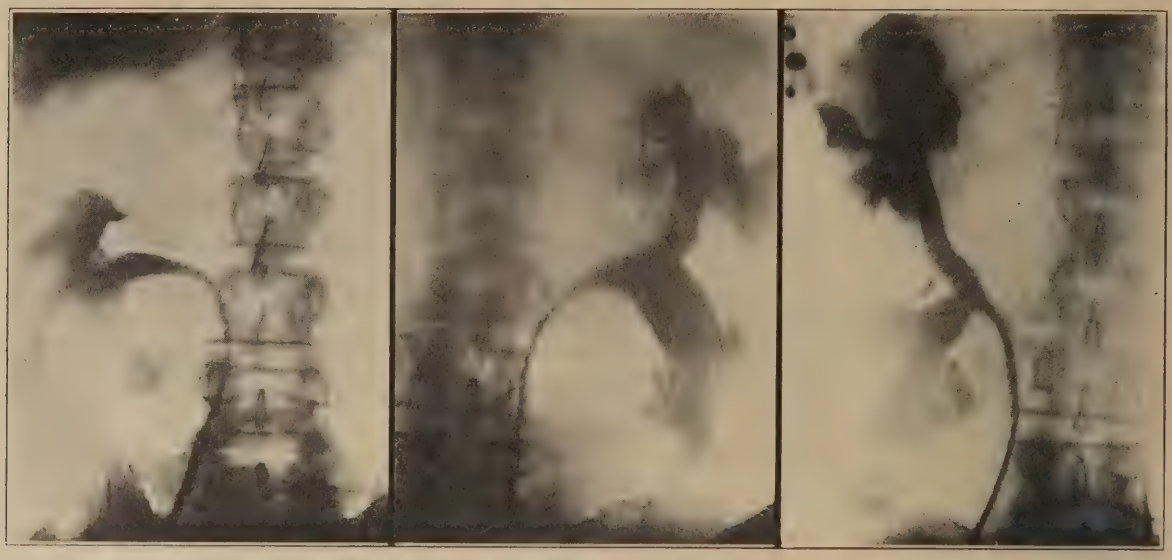

Fig. 1. Fig. 2. Fig. 3.

Fig. 1.—Normal pyelogram and ureterogram. The catheter has been withdrawn entirely from the ureter in all the illustrations. The kidney, pelvis and ureter are seen clearly outlined by the solution of sodium iodide.

Fig. 2.—Postpartum pyelitis; pyrexia, pyuria; stricture of the ureter. Practically all of these cases have stricture of the ureter. Note the fairly extensive stricture just above the bladder, with dilated and tortuous ureter above it. Note also the moderate degree of hydronephrosis with poorly defined calyces. This patient was promptly relieved by catheter drainage and pelvic lavage, and the pyuric cleared up after ureter dilatations and pelvic instillations.

Fig. 3.—Multiple strictures, moderate hydronephrosis. Calculus in pelvis which does not show in this picture, since it is covered by sodium iodide. Pyelotomy, followed by dilatations and instillations. These are the cases in which symptoms persist and calculi recur if the strictures are not dilated.

which he was able to report a large number of cases successfully treated, many of them with brilliant results. This time he went a bit farther and maintained that stricture of the ureter was one of the most common of all surgical diseases of the urinary tract and also made the point that in many cases where stricture and calculus were found together that the stricture was the primary lesion and the calculus a result and complication, instead of the other way about, as was commonly supposed. He also emphasized the importance of looking for and treating strictures after removal of calculus in order to ensure against a continuance of symptoms or a recurrence of the calculus. This paper was warmly received and the discussion was practically without exception favorable. Hunner had made his point and a new disease, having passed through the usual baptism of time and adverse criticism, had taken its place on our list.

One item which perhaps more than any other has served to prevent an earlier and more general recognition of this important subject is the fairly reasonable demand on the part of the critics that before accepting the proposition they must have the actual pathology demonstrated either at the autopsy or operating tables. Critics also remarked that stricture of the ureter was rarely if ever noted as part of the record of a complete autopsy. This last item is readily answered by the simple statement, which I believe is reasonably correct, that socalled complete autopsies rarely if ever include a careful investigation of the ureter unless attention is focused upon this organ. The cases in which this lesion is recognized rarely come to autopsy while the disease is under consideration, and if properly treated they rarely come to operation. Recently Hunner has reported a few cases which had been demonstrated at operation. I have had one in which complications arose demanding a laparotomy. At this time it was very easy to feel a thickened ureter wall at the site of the stricture.

Stricture of the ureter may occur at any point throughout its course, but is found most commonly in the lower third. They may be single or multiple and they are frequently bilateral. They occur as a linear constriction or may involve two or more inches of the ureter. The pathology I assume to be identical with stricture noted in any of the hollow organs, round cell infiltration, fibrosis representing the end result of inflammation, contraction and resulting diminution in caliber. Stricture of the ureter implies a preceding ureteritis at the point of the stricture. This may have occurred in the immediate or remote past, and may come about in one of several ways. I believe the etiological factors may be conveniently arranged in three or four groups. The first group, which probably includes the greatest number, includes those instances in which there has been a direct extension of inflammatory processes from neighboring organs, such as the bladder itself, the broad ligament in the female and the seminal tract in the male, the sigmoid on the left, and the retrocecal or pelvic appendix on the right in either sex. This infection may be by direct contact or through the lymphatics. As noted this lesion occurs most frequently in the lower third of the organ, and you will remember that the ureter passes through the broad ligament in the female and in close relation to the seminal vesicles in the male. Infections in these structures are of course common and generally recognized.

The second group represents the scars left after one or more attacks of pyelonephritis and ureteritis, many of which occur and pass unrecognized in infancy. We can all recall numerous more or less obscure febrile movements occurring in children which are relieved by bowel irrigation and some febrifuge containing among other things potassium

citrate. A careful urine examination in many of these cases would establish a diagnosis of pyelonephritis. These cases usually make prompt recovery but may and I am sure often do have scars remaining which produce symptoms in later years. Of course, at the present time, as a result of more careful urine examination in children these cases are promptly recognized, and with the employment of appropriate measures most of them respond promptly to treatment. In my opinion the few who do not respond are already beginning the formation of stricture and the trouble persists simply because one of the first principles of the treatment of any infection is overlooked. I refer of course to adequate drainage.

FIG. 4.—Acute pyelitis of one week's duration, beginning with colicky pain and hematuria. Note stricture partly hidden by bladder shadow, dilated, tortuous ureter above. Cured by catheter drainage and lavage, and later dilatations.

A third group includes blood borne infections from remote foci of infection, such as teeth, tonsils, and other structures. It may seem a bit fantastic to consider an infection being carried from a tooth root to some particular segment of the ureter, yet it is no more remarkable for this to occur than it is for the infection to be carried to the kidney or knee joint, or to produce a boil in some particular spot on the back of the neck.

One might add a fourth group including congenital narrowing such as is occasionally noted at the ureter meatus or the intramural portion of the ureter.

This paper does not include a consideration of stricture by tuberculosis, nor does it include kinks. These cases should be considered as an entirely separate problem.

The clinical symptoms are similar to those of ureter calculus and are just as variable. Some cases will present as the only symptom repeated attacks of ureter colic with entire absence of any symptoms in the interim between attacks. I have had several such cases, all of them readily and permanently relieved by dilatations. Frequency and urgency of urination may be the most prominent or only symptom noted, stricture of the ureter should be borne in mind as a possible factor in searching for a cause of this annoying complaint. The greater number of patients complain of a dull pain in the groin which may or may not be referred along the course of the ureter to the meatus or down the inner side of the thigh. This pain is usually fairly constant and steady, although there may be minor exacerbations such as are frequently noted during the menstrual epoch. The urine may or may not be infected. It is well to remember that clear sterile urine does not exclude stricture. When hydronephrosis exists as a complicating feature there may be a dull pain in the loin occasionally referred through to the corresponding hypogastrium. Some cases may present all of these symptoms at one time or another. Not infrequently reflex digestive disturbances of one sort or another are noted. This fact should be borne in mind when considering a possible diagnosis of that definite but much overworked lesion, chronic appendicitis. Many, perhaps most of these patients, will show an area of tenderness to deep palpation along the outer border of the rectus muscle for a short distance above and below the sacral promontory. This area is rather mesial to the point of greater tenderness noted in cases of appendicitis, and above that noted in tubo-ovarian trouble.

This brief outline of the symptoms and etiology is enough to attract our attention to the possibility of ureter stricture if one but bears it in mind. I do not pretend to say that every patient presenting this clinical history is suffering from stricture of the ureter, but I do maintain that every patient with such a story is entitled to a thorough and careful investigation for the purpose of confirming or refuting such a possibility. The diagnosis, once sus-

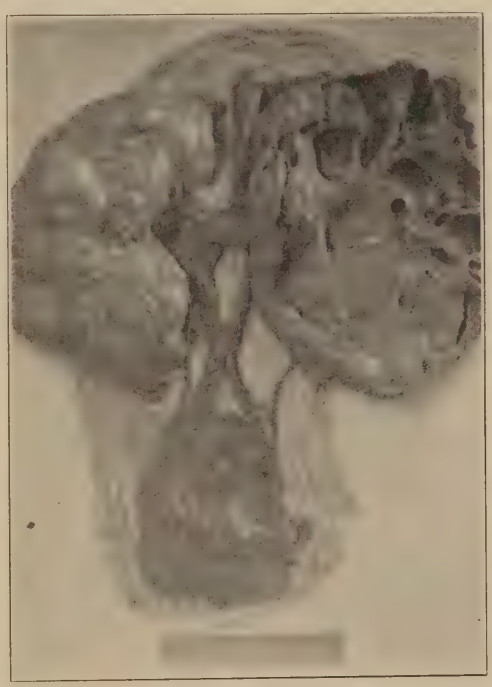

FIG. 5.—Multiple strictures—pyonephrosis requiring nephrectomy—a late case. This kidney could have been saved if seen earlier.

pected, is readily made. Hunner makes his diagnosis with a wax tipped bougie. The instrument is passed through a Kelly type of cystoscope into the ureter and beyond the point of obstruction. Upon its withdrawal one feels the catch or hang exactly as it would be felt with an olivary bougie in stricture of the urethra. This method is not so practicable in the lens type of water cystoscope in common use. I make my diagnosis by a combination of x ray and cystoscopic examination. An opaque catheter is passed to the kidney pelvis on the side under suspicion and a radiograph is made with the catheter *in situ*. The kidney pelvis is then filled with an opaque solution such as sodium iodide, fifteen per cent., and another exposure made of the kidney pelvis. The catheter is then gradually withdrawn, instilling at the same time enough of the opaque solution to distend the ureter, and another picture made including the renal pelvis and the whole length of the ureter. This gives a picture of the distended ureter, and points of narrowing and angulation are readily noted. Some of our critics say that these points of narrowing represent peristaltic waves. Perhaps some of them do, but when they occur at repeated examinations in the same spot, the evidence of stricture seems to my mind convincing. This method of examination also provides us with an opportunity to make a careful survey of the whole urinary tract, including differential functional tests, careful urine examinations, etc. This I believe is essential and should be done in every case.

The treatment of stricture of the ureter is gradual dilatation, exactly the same as treatment of stricture of the urethra, except that it must be done through a cystoscope. It may be necessary to start with a filiform bougie, gradually increasing the size up to a 6, 8, 10, or 12 French, depending upon the requirements of the individual case. It is well after each treatment to instill a small quantity of twenty-five per cent. argyrol.

Treatments may be repeated at intervals of one, two, three, or four weeks, depending upon the tolerance of the patient to cystoscopic manipulation. This procedure is carried out in the office and usually entails little discomfort on the part of the patient. Not infrequently, however, it is followed by a more or less sharp reaction, coming on a few hours after the treatment and lasting for several hours or several days. This reaction takes the form of tenesmus and pain over the kidney and ureter. It is readily relieved by the usual measures.

Many of these patients appear to be permanently relieved by one or two treatments. In fact my attention was rather forcibly directed to this matter several years ago by many patients who presented themselves at my clinic complaining of pain in the loin and some frequency of urination. We would put them through our routine examination including careful cystoscopic and x ray studies, the latter including a pyelogram, but not, at that time, a ureterogram such as we do at present. They would be asked to return a few days later for a report on the examination and advice as to treatment. A careful survey of all our findings might be essentially negative and we felt that we had failed to establish a diagnosis. Nevertheless they would return at the appointed time and volunteer the information that, whatever we had done, we had cured them. This happened not once but many times, and we feel reasonably certain now that these patients were suffering from a stricture of the ureter, and that they were temporarily at least relieved by the simple passage of a catheter.

Many patients are not so fortunate, and require repeated treatments over a period of several months. It is well in all cases to have them report for treatment at gradually increasing intervals for a few months after the relief of symptoms in order to ensure against a recurrence of trouble.

SUMMARY

Stricture of the ureter independent of any other surgical lesion of the urinary tract occurs commonly. It is easily diagnosed and responds readily to simple nonoperative treatment. If neglected it may and often does lead to hydronephrosis, pyonephrosis, and eventual destruction of the kidney. Failure to recognize it has resulted in countless numbers of needless and useless operations.

The Male Climacterium; Its Clinical Significance and Treatment

MAX THOREK, M.D.,
Chicago, Ill.

The word climacteric is derived from the Greek *Klimakter,* meaning a step of a stair or ladder which was used to designate a dangerous period in life, and was originally equally applicable to either sex although it has been customary to apply it only in the case of the menopause in females.

It is an established anatomical fact that the early methods of embryonic life show no sexual differentiation, and that the cellular elements that ultimately undergo variation and develop into the sexual apparatus of male and female are indifferently present in either sex not only up to a certain period of intrauterine life, but in a rudimentary form throughout the entire period of human existence.

Since it must be admitted that the sexes begin and end life in marked similarity, the period of differentiation commences at puberty, and this suggests that the second change, or the change that brings the sexes together again, occurs at about the same epoch after puberty in both sexes. At about the menopause age in woman, man also becomes unstable from a mental and nervous viewpoint, and although he has no menstrual flux, as in the case of females, he does show every other symptom, mental and physical, that characterizes the change in the female.

The man at this period has reached an age when functional vitality ceases to be sufficient to properly

invigorate all his organism as in his younger days. He gives evidence of exhaustion in line with the physiological law that the last to develop is the first to show evidence of decadence. The man has reached his climacteric.

Sanctorius (1) seems to have been the first to mention the climacteric in connection with men in 1728. From the viewpoint of body weight he found that in men there was a monthly increase of one or two pounds followed by an increase in urinary output and accompanied by lassitude and a feeling of heaviness; this suggested a monthly cycle in the organism of men.

According to A. Church (2) the monthly increase of weight in men was confirmed by Belfield of Chicago, who also observed a phosphaturia analagous to that experienced by women just before menstruation.

The accepted real climacteric period or menopause which may be regarded as coinciding with life's full maturity is a well recognized event in the life of women, but it is not so generally appreciated that men go through a similar readjustment of tissues though after a less dramatic method and probably at a somewhat later age. The cessation of menstruation in women results from the functional death of the ovaries; it is usually accompanied by disturbance of the vasomotor and nervous systems as well as being a time of special likelihood to the development of disease or for the manifestations of disease previously more or less latent. In men at a period of life from about seven to ten years later than the onset of the menopause in women there is a similar susceptibility to the awakening or arousing of latent diseases and there seems to be at that period, just as is the case in women, an upset in tissue equilibrium conducive to the establishment of pathological conditions.

Halford (3) in 1831 noticed and described conditions in men which he termed climacteric diseases. Others asserted that there were rhythmic changes in the blood pressure in both sexes at definite periods. That some relation exists between certain critical ages in life and the activity of the sexual functions has long been maintained. In both male and female the fifteenth year corresponded approximately to puberty and in women the forty-second or forty-ninth year is not uncommonly the date of the menopause.

In man at the age of sixty-three—his *grand climacteric*—some assume that owing to the cessation or marked diminution of the activity of the testicles a profound change takes place in the body, and that this change corresponds closely to that supposedly dependent on the more sudden alteration in the function of the ovaries at the menopause in women.

An editorial (4) in discussing the male climacteric remarks "that certain tolerably characteristic symptoms, not unlike those presented by women in the change of life, are undoubtedly manifest in many men about the age of sixty-three will be vouched for not only by physicians in general practice but also particularly by nerve specialists to whom these patients turn for relief. Attention has been focused on these symptoms by Mendel (5) when he speaks of the "climacterium virile" with lack of emotional control and a tendency to shed tears, combined with outspoken signs of depression, disinclination for exertion, lack of will power and irritation; other symptoms sometimes prominent being dizziness, sense of pressure in head, hot flushes and palpitation of the heart."

In connection with these observations the question at once arises whether these symptoms are, in reality, due to a disturbance in the internal secretion of the testicles, or whether they can be the result of the arteriosclerosis which develops almost with regularity at about this age; and if there may not be a relation between testicular function and vascular integrity in the male. Such questions are not easy to answer.

The defenders of the doctrine of the sexual origin of the male climacteric point to the nervous, emotional and vasomotor phenomena which follow castration analogous to menopause symptoms which are brought about artifically in women by bilateral oöphorectomy. The objection that the natural male climacteric may depend upon arteriosclerosis rather than upon retrogression of the activity of the sexual glands is met by the argument that the arteries are not always sclerosed when the climacteric symptoms are met in man; and that when they are, such sclerosis might be considered as evidence of the importance of the internal secretion of the testicles for the normal reglation of the circulatory apparatus and for the welfare of the general metabolism.

Other opinions while regarding the symptoms referred to as dependent upon anomalies of internal secretion suggest that they owe their origin not to changes in the functions of the testicles alone, but in addition, to alteration in the activities of other related glands, notably the prostate. It seems unquestionable that some functional connection exists between the prostate and the testicle.

The large amount of investigations carried out within recent years showing the nature and functions of the internal secretion of the interstitial cells of the testicle renders it extremely probable that the climacteric changes in the organism of man are mainly dependent upon changes in this secretion. The senile organism manifestations are generally accompanied by impotency even though sexual desire persists. The diminution of vital capacity, with lessened activity of secretory and excretory vigor is a clinical manifestation that life has crossed its summit and that the bodily organism has entered upon the downward grade of its duration.

Acute illness in man or woman occurring within the limits of the climacteric is attended with more than the usual risks, the resisting powers of the organism being then apparently less competent to battle with infective or toxic invasion. But it is the chronic ailments existing at this period of life that demand the closest attention and interest. There are certain of them that, on account of their frequency, stand out conspicuously. Growths of all kinds, previously slow, at this time show great activity. Arteriosclerosis, interstitial nephritis, and diabetes form a group of diseases which, with surprising frequency, become manifest in men between the ages of fifty-five and sixty-five. These conditions no doubt existed for a long time, but probably their development was checked by agencies charged with general defensory powers as well as with the

maintenance of virility in the organism. The weakening of such defences at the period of the climacteric gives these chronic ailments referred to full opportunity to progress unchecked. The man may not feel ill but he is easily tired and quite unfit for the amount of exertion previously habitual to him. Although he eats and digests fairly he fails to keep his nutrition to the correct mark and he appears emaciated. He no longer has the same grip on things.

In such men a process of sclerosis is probably being effected which reacts on the particular tissues determined by personal tendencies or inherited qualities. The common antecedent in all cases is strain continued almost incessantly for fifty years. Domestic straits, financial worries, emotional storms and mental anxieties, enter into the lives of those who are strenuous and ambitious to achieve worldly success. The stress and strain fall primarily upon the nervous centres which become devitalized and unable to control organic functions.

None of the organs of nutrition and elimination are any longer equal to their task, a fact which is all the more important seeing that many such men have been habitually good eaters and that but few have taken exercise of any kind. The slowed nutrition, autointoxication, and the diminished vitality with neuropathic symptoms are the manifest symptoms of the failure of some governing power regulating the organic processes and which, as stated, are most probably, as far as our present knowledge goes, connected with the failure of internal secretions.

Neurologists are too prone to concentrate attention upon the psychical aspect of these cases, but what the patient needs is careful advice concerning the nature of the male climacteric and the changes that accompany it. The marvelous effects which in many cases have followed testicular transplantations in the senile point to this method of therapy as that which offers the most hopeful relief in this field.

Thewlis (7) refers to a typical case of the senile climacteric in a man of seventy-three years. In this case the principal change observed was in the mentality. Mental deterioration proceeded rapidly but irregularly, the usual mental attitude being agitated and depressed. This man also showed sexual recrudescence, the object of his sexual desires being a middleaged married woman. Six months after the initial manifestations of the senile climacteric in this patient he is passing out of this period into the somatic state of senility and the mental state of senile dementia. His appearance bears out the statement of his friends that he aged ten years in six months. His bearing is less erect; he has lost weight; his face is wrinkled; his expression is apathetic; he is careless about his person, etc., his walk is slower. The degenerative changes have been quite uniform.

During the climacteric this man showed maniacal outbursts, periods of depression and amentia; there were delusions, hallucinations and phobias with lucid intervals. The mental aberrations gradually disappeared leaving a weakened mind, the true dementia. The sexual recrudescence entirely subsided.

Thewlis says that the senile climacteric being one of the physiological critical periods it cannot be prevented nor need anything be done if the mental and physical deteriorations proceed uniformly and no active or distressing manifestations appear.

In considering the therapy of patients suffering from the effects of testicular retrogression and consequent clinical manifestations resulting in the symptom complex discussed in this paper, two indications for treatment present themselves. In the first place, a thorough investigation of the physical status of the patient is essential. We must endeavor to eliminate the presence of organic disease of all sorts and rectify metabolic digressions which, in themselves, may give rise to symptoms analogous to those under consideration, in which case it would, of course, be wrong to advise or do anything other than eliminate or ameliorate the existing pathological process responsible for the patient's objective and subjective manifestations. Should there be no organic disease, nutritional disturbance or other factor responsible for the patient's condition, and if the diagnosis by a process of elimination directly points to endocrine disturbance, then two avenues of relief are open.

First.—Attempts at vasoligation, in which event the patient should be apprised of the operative trauma that is to be inflicted upon his vas deferens and consequent sterilization of the corresponding testis; and if, after he is made to understand the possible advantages and frequent failures of the operation his consent is obtained one may occasionally obtain good results from this procedure.

On the other hand, if the case be one where there is distinct gonadal pathology often a homotransplant from a near relative of the patient or other human material or, perhaps, a heterotransplant from the higher anthropoids should be advised. If, in addition to gonadal dysfunction, thyroid inefficiency is found, (let it be said at this juncture that a metabolism test is always desirable in cases of this class and very often will throw light on an otherwise obscure field) then in conjunction with transplantation, thyroid therapy either by transplantation or per os, is clearly indicated. In aberrations of other endocrines, clearly manifest in a given case by specific manifestations incriminating a given gland of internal secretion, the addition of therapeutic resource directed to that gland is clearly indicated.

CONCLUSIONS

A series of cases carefully studied by me leads me to the conclusion that every case must be judged upon its own merits and the indications present. A great deal of good may be accomplished in these cases, which is of real value, and the psychic element can be entirely eliminated in many instances. It must, of course, be kept in mind that the results are not uniformly good and patients must be subjected to therapy of one type or another to meet the symptoms for which they apply for relief. The justification of the gynecologist and urologist for submitting their female patients for the relief of the untoward manifestations of the climacteric to various forms of therapy holds good in the male. Thus far this field has been sadly neglected and offers much for the class of patients who travel from consultation chamber to consultation chamber and finally fall into the hands of quacks or faith healers with ultimate and often untimely destruction, when in well selected instances the physician can accomplish a great deal by the suggestions as to therapy given in this paper.

Changes in the Mechanism of the Human Heart Preceding and During Death

FREDRICK A. WILLIUS, M.D.,
Rochester, Minn.
Section on Medicine, Mayo Clinic

The observations in this study are based on six patients in whom almost continuous electrocardiographic records were obtained from ten minutes to seven hours and thirty-two minutes preceding death. Opinion has been rife with regard to the final mechanism of the heart at death, but actual proof has been meagre. It is generally conceded that ventricular fibrillation is incompatible with life, the evidence for this arising from the experimental data of numerous observers which has led to the belief that this disturbance in cardiac action is usually the terminal mechanism in the death of human beings. Instances of recovery from ventricular fibrillation in cats (3) and dogs (4) have been reported, as well as temporary recovery in man (6, 7).

Robinson, in 1912, published a study similar to this in which electrocardiographic observations were made on seven patients dying of acute infectious disease. He found that in four of his patients activity of the ventricles was evident one and one half to eighteen minutes after auricular activity had ceased, and in two activity of the auricles outlasted that of the ventricles. Complete heart block occurred in three instances, while slight delay in conduction was observed in five. In two instances auricular activity ceased before evidence of impaired conduction appeared. Marked slowing in rate was noted constantly; the slowest independent ventricular rates varied from 13.6 to 47 each minute and the slowest recorded regular auricular rates varied from 20 to 65 each minute. Ventricular fibrillation occurred in only two cases and in one of these, normal rhythm was temporarily reestablished. A constant finding was the eventual fusion of the R and the T wave, giving rise to a large rounded or a peaked wave. There was no instance of auricular fibrillation in Robinson's cases. A very interesting observation was the fact that evidence of cardiac activity was registered by the electrocardiograph from six to thirty-five minutes after all the usual clinical signs of death had occurred. This observation has been confirmed by Einthoven and Hugenholtz, who found during the course of animal experiments that the electrocardiogram continued after the recording index had ceased to register muscular activity.

Greene and myself in the Mayo Clinic, in experimental work not yet published, studied the mechanism of death in the dog's heart. The animal was anesthetized by ether, using the intratracheal insufflation method. Electrodes were applied to the right foreleg and the left hind leg to obtain the electrocardiograms in Derivation II. The heart was exposed by a sweeping intercostal incision, and the wound spread by retractors, giving a large unobstructed field. After obtaining a control electrocardiogram, all the vessels leading to and from the heart were simultaneously and completely clamped, and continuous electrocardiograms obtained until all signs of cardiac activity had ceased.

In all instances a progressive slowing in cardiac rate was noted, ventricular activity outlasting that of the auricle in every case. The various types of nodal rhythm occurred and, as slowing became more marked, sinoauricular block, delayed auriculoventricular conduction, and complete heart block appeared. Extreme degrees of complete heart block were noted; in one animal a strip of tracing revealed forty-five auricular waves to one of the ventricle. The stage of block was invariably followed by the fusion of the R and the T waves, resulting in a peculiar, distorted wave of rather high amplitude. The rate during these latter phenomena was extremely slow, often only twelve complexes during the minute and, after a variable period of time, all evidence of cardiac activity ceased. Ventricular fibrillation was frequently observed. The same experiments were repeated with the vagi divided, as they lay in the carotid sheath. This procedure was not followed by the appearance of nodal rhythm, nor did the preliminary stages of heart block appear.

Similar observations were made by Greene and Gilbert, working on dogs in whom they studied the behavior of the blood pressure and the electrocardiogram during extreme oxygen want. After sec-

Auricular flutter, sinoauricular block and idioventricular rhythm. *l*. Two and four tent seconds later. Delayed A-V conduction and sinoauricular block. *m*. 10.40 p. m. Partial block 2.1. *n*. 10.41 p. m. Complete block. *o*. 10.4 p. m Cardiac standstill for 11.4 seconds. *p*. Five and two tenths seconds later. Fusion of R and T waves resulting in peculiar rolling com plexes. *q*. Continuous with preceding tracing. Ventricular fibrillation. *r*. One minute, 3.04 seconds later. Ventricular fibrillation and cessati of cardiac activity. All electrocardiograms are recorded in Derivation II.

tion of the vagi, they likewise noted the disappearance of nodal rhythm and heart block in the electrocardiogram.

Two factors are apparently at work in the dying heart: 1, the factor exerting influences through the vagi affecting the cardiac pacemaker, resulting in various types of nodal rhythm; affecting the auriculoventricular bundle with the development of varying degrees of heart block and, in a degree, slowing the cardiac rate, and 2, the factor which disturbs the inherent automatism and fundamental coordination of the heart, as evidenced by high degrees of heart block, cessation of auricular activity, periods of complete cardiac standstill, and the fusion of the ventricular components.

It is probable that the extreme oxygen want accompanying cardiac asphyxia is capable of producing marked stimulation of the vagi, giving rise to the disturbances of the cardiac pacemaker and of the auriculoventricular bundle. As the processes of death progress, the inherent activity of the heart is affected, and the final ventricular events appear as already described.

CLINICAL CASES ILLUSTRATIVE OF THE MECHANISM OF DEATH IN THE HUMAN HEART

Case I (A30600).—A man, aged fifty-eight years, had had dyspnea and palpitation following exercise for three years. During the last seven months th patient had felt fatigued and intermittently had ha fever, at times as high as 103° F. At the time o examination he had a septic type of temperature He had had a severe attack of acute inflammator rheumatism in 1914, and again three years befor examination.

Examination revealed the heart to be enlarged, th cardiac dullness extending 4.5 cm. to the right an 15 cm. to the left of the midsternal line. There wa no arrhythmia, but a loud blowing systolic murmu was audible at the apex, transmitted into the axill and heard through to the back. The edge of th liver was palpable four cm. under the right costa margin, and the spleen was just palpable. The sys tolic blood pressure ranged from 156 to 162, and th diastolic was 78. The pulse ranged from 100 t 110. Blood culture studies revealed the presenc of the Streptococcus viridans. Hemoglobin was 4 per cent. erythrocytes numbered 2,210,000, an leucocytes 6,200. Repeated urinalyses revealed small amount of albumin, occasionally a few hyali casts, and erythrocytes. The combined phenolsul phonephthalein test varied from five per cent. to te per cent. There were 124 mg. of urea in each 10 c. c. of blood. The electrocardiogram revealed noda premature contractions.

A clinical diagnosis was made of subacute bac

erial mitral endocarditis (Streptococcus viridans), hronic nephritis, secondary anemia and peripheral rteriosclerosis. Six days before the patient died he uddenly became hemiplegic and sank into coma rom which he did not arouse.

Necropsy revealed chronic endocarditis of the itral valve and right auricle with acute vegetative xacerbation. There was considerable hypertrophy nd dilatation of the myocardium with fatty changes. he kidneys revealed chronic diffuse nephritis with yelitis. There was a splenic infarct, an advanced egree of arteriosclerosis, and a terminal broncho-neumonia.

Analysis of electrocardiogram.—The first records f the series were obtained at 9:45 p. m., when death ppeared imminent. The rhythm was of sinus origin ith a moderate degree of tachycardia, 110 each inute (Table 1, Fig. 1a). No appreciable change as noted forty minutes later (Fig. 1b). Six min-tes later, however, a marked slowing in the heart ite was noted, varying from 86 to 37 each minute, ith the development of nodal rhythm (R-P on re-ersed rhythm type). The P wave which, prior to is, had been positive, became negative and of lower nplitude (Fig. 1c). This mechanism remained un-tered until 47.8 seconds later, when periods of omplete block and sinoauricular block appeared. The P wave remained negative (Fig. 1e). One minute later the onset of bundle branch block was noted, the QRS complexes, suddenly broadening out from 0.03 to 0.16 seconds, were negative, and of increased amplitude. At this point auricular activity could not be identified with certainty (Fig. 1g). Bundle branch block persisted for about three minutes and was succeeded by auricular flutter with varying degrees of block (Fig. 1i). One half minute later the flutter was replaced by sinoauricular block followed again by idioventricular rhythm (Fig. 1j). After 2.4 seconds delayed A-V conduction was noted (0.24 second) and sinoauricular block again appeared (Fig. 1k). About one half minute later 2:1 block occurred (Fig. 1l), followed in one minute by complete block (Fig. 1m). One minute later no sign of cardiac activity was evident for 11.4 seconds (Fig. 1n). After 5.4 seconds fusion of the R and T waves occurred resulting in large, peculiar, rolling complexes (Fig. 1o), followed immediately by a period of ventricular fibrillation and then complete cessation of all signs of cardiac activity (Fig. 1p). Auricular activity ceased two and one half minutes before that of the ventricles. The slowest recorded ventricular rate was 21, while the slowest auricular rate was 22 each minute.

Case II (A404109).—A man, aged forty-three years, complained of dyspnea, palpitation, tachycardia, progressive weakness, and loss of weight of six months' duration. He was extremely nervous and irritable, and at the time of his admission to the hospital was very emotional.

Examination revealed marked emaciation, marked tremor of the hands, warm, moist skin, and profound

TABLE 1.—Detailed analysis of electrocardiograms in Case I, A30600.

quadriceps weakness. There was a slight degree of exophthalmos. The thyroid was slightly, but diffusely, enlarged, of granular consistency, and thrills and bruits were present at all thyroid poles. The heart was slightly enlarged, the cardiac dullness extending 4 cm. to the right and 13 cm. to the left of the midsternal line. A blowing systolic murmur was audible at the apex, not transmitted. A total arrhythmia was present. The cystolic blood pressure was 158, the diastolic 84, and the pulse rate 120. Urinalysis revealed only a faint trace of albumin. The hemoglobin was 65 per cent., erythrocytes numbered 3,780,000, and leucocytes 4,400. The basal metabolic rate was +72 per cent. The clinical diagnosis was severe exophthalmic goitre. The patient became progressively worse and died of acute hyperthyroidism two weeks after admission.

Necropsy revealed bronchopneumonia of the right lung, marked dehydration of all tissues, old healed pulmonary tuberculosis, and pleuritis.

Analysis of electrocardiograms.—The preleth records were begun at 8 p. m., and the initial tra ing revealed an extremely rapid auricular fibrillatio 222 each minute (Table 2, Fig. 2a). One hour an twenty-two minutes later the rhythm was regula and of sinus origin, the rate being 192 (Fig. 2b

TABLE 3.—Detailed analysis of electrocardiograms in Case III, A406471.

One hour and eight minutes later the rate was 200, the rhythm regular, but all complexes had much greater amplitude (Fig. 2c). After two hours and five minutes, the heart rate suddenly slowed to 72 each minute, with the inception of nodal rhythm (disappearance of P wave) (Fig. 2e). The next record, taken 41.4 seconds later, revealed a migrating pacemaker, the relationship of the P to the R wave constantly shifting (Fig. 2f). About one minute later complete block supervened (Fig. 2h) and 4.8 seconds later there was no evidence of auricular activity (Fig. 2i). The record taken 23.4 seconds later revealed only two ventricular complexes followed by cessation of all cardiac activity. The auricles ceased to show evidence of activity 28.2 seconds before the ventricles. The slowest recorded ventricular rate was 14, while the slowest auricular rate that could be determined was 60 beats each minute.

CASE III (A406471).—A woman, aged twenty-nine years, was admitted to the hospital suffering severely from cardiac decompensation. Ten years before, she began to have shortness of breath and palpitation on exertion, and occasionally swelling of the ankles and legs. During the last year her condition became progressively worse and she was admitted to the hospital in a critical condition.

On examination the patient was found to be very sick, markedly dyspneic, with quite profound cyanosis and marked edema of the lower extremities. The cardiac dullness extended five cm. to the right and fourteen cm. to the left of the midsternal line. Total arrhythmia was present. Loud blowing to and fro murmurs were heard over the cardiac area, and the systolic murmur was transmitted into the axilla. A pulse deficit of 110 beats each minute was recorded. Examination of the lungs revealed many moist râles. The liver extended down to the level of the umbilicus. The systolic blood pressure was 116, and the diastolic 90. The electrocardiogram showed auricular fibrillation and preponderance of the right ventricle. A clinical diagnosis was made of chronic mitral endocarditis with stenosis and regurgitation, chronic myocarditis with auricular fibrillation, and passive congestion of the viscera.

Necropsy revealed chronic endocarditis of the mitral valve with considerable narrowing of the ring, and hypertrophy and dilatation of the myocardium (300 gm.). There was a terminal thrombosis of the left auricle. The liver weighed 1,150 gm. and showed marked evidence of cirrhosis. An infarct of the right kidney and terminal bronchopneumonia were also noted.

Analysis of electrocardiograms.—This patient died rather suddenly, and therefore records over a prolonged period were not available. The first tracing taken at 10:08½ a. m., revealed auricular fibrillation with complete block (Table 3, Fig. 3a). One minute later complete cessation of cardiac activity occurred and lasted for 11.4 seconds (Fig. 3b). Following this there were occasional signs of ventricular activity (Fig. 3c, d, e), followed by a brief period of ventricular fibrillation (Fig. 3f), nine and one half minutes after our observations were begun. The slowest sequential ventricular rate recorded was

Time	Rate: Ventricle	Rate: Auricle	Conduction time (Seconds): R-R	P-R	QRS	S-T	T	Wave amplitude (10^{-4}) (Voltage): P	Q	R	S	T	Remarks

nineteen beats each minute. Auricular activity ceased eight and a half minutes before ventricular.

Case IV.—(A410137). A woman, aged thirty-four years, was admitted to the hospital in delirium attending an acute crisis of exophthalmic goitre.

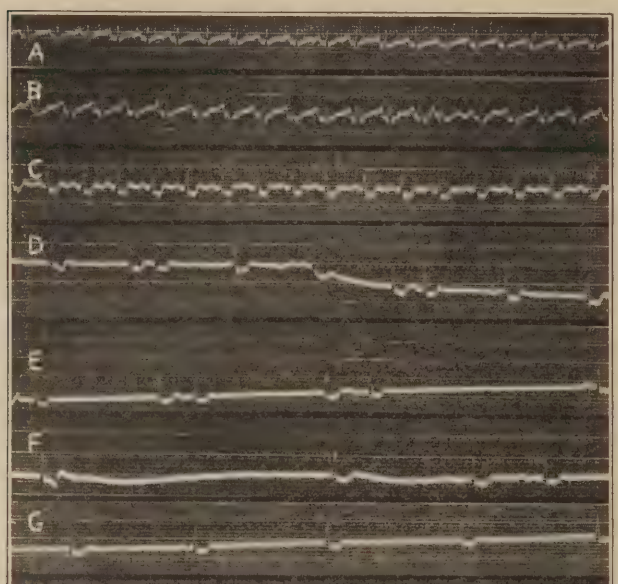

Fig. 4 (Case 4, A410137). *a.* 9.45 p. m. Regular sinus rhythm. *b.* 1.00 a. m. One nodal premature contraction. *c.* 10.40 a. m. Regular sinus rhythm. *d.* twenty-one seconds later. Nodal rhythm (P-Ro) and nodal premature contractions. *e.* Continuous with preceding tracing. Nodal rhythm, nodal premature contractions and sinoauricular block. *f.* Continuous with preceding tracing. Migrating pacemaker and cessation of auricular activity. *g.* Continuous with preceding tracing. Cessation of auricular activity. *h.* Continuous with preceding tracing. Short period of ventricular fibrillation and cessation of cardiac activity.

She had been perfectly well until four months before.

Examination was difficult, owing to the patient's extreme restlessness. There was a slight degree of exophthalmos, the thyroid was slightly enlarged and firm, and loud bruits were audible over the poles. The size of the heart could not be determined with any degree of certainty, the rhythm was regular, and no murmurs were audible. The systolic blood pressure was 140, the diastolic 56, and the pulse rate 120. The basal metabolic rate could not be determined, owing to the patient's extremely serious condition. A clinical diagnosis of acute crisis of exophthalmic goitre was made.

Necropsy revealed moderate dilatation of the left ventricle with slight fatty changes in the myocardium. The lungs showed acute emphysema; generalized congestion and persistence of thymus gland.

Analysis of electrocardiograms.—The first record obtained was at 9:45 p.m., and showed a rapid regular sinus rhythm, the rate being 190 each minute (Table 4, Fig. 4a). At 1:00 a. m., the rate was still rapid, 180, and the regular rhythm was occasionally interrupted by nodal premature contractions (Fig. 4b). No appreciable change was noted until 10:40 a.m., when the rate suddenly slowed to 85 beats each minute with the inception of nodal rhythm (P-R-o), and nodal premature contractions were present (Fig. 4d). Almost immediately the rate slowed further to 53, with the advent of sinoauricular block (Fig. 4e) and immediately migration of the pacemaker was evident (Fig. 4f). Auricular activity then ceased (Fig. 4g), followed by a short period of ventricular fibrillation, and then no evidence of further cardiac activity was noted (Fig. 4h). Auricular activity ceased 14.8 seconds before that of the ventricles. The slowest recorded sequential auricular rate was 150, while the slowest regular ventricular rate was 40.[1]

SUMMARY OF ELECTROCARDIOGRAPHIC FINDINGS

In every instance auricular activity ceased before that of the ventricles; the shortest duration was fourteen and eight tenths seconds, the longest eight and one half minutes. The slowest recorded sequential auricular rate was 22, while the slowest ventricular rate was 14 (Table 5). Two patients at the beginning of the graphic studies had auricular fibrillation, but this disorder of cardiac mechanism did not occur as an intercurrent event. Nodal rhythm occurred in five cases; there were two instances of the reversed rhythm type, two instances of simultaneous contraction of auricles and ventricles (P-R-o), and one of diminished P-R interval associated with the P-R-o type. Three instances of complete heart block were noted, while sinoauricular block occurred twice, and delayed auricuoventricular conduction and partial heart block once. One patient exhibited a period of auricular flutter with varying degrees of heart block. In two cases, periods of pacemaker migration were present. There were two examples of the bizarre complexes of idioventricular rhythm. In three cases long periods of complete cessation of cardiac activity occurred, 9.4 seconds 9.4 seconds and 11.4 seconds respectively. Ventricular fibrillation occurred in four cases, being the terminal mechanism in three. Fusion of the R and the T waves was noted in three cases.

The changes occurring in the mechanism of the human heart preceding and during death are variable

Disorder of cardiac mechanism	Robinson's series	Willius' series
Cases	7	6
Ventricular activity outlasting that of the auricles	4	6
Auricular activity outlasting that of the ventricles	2	0
Auricular fibrillation	0	2
Complete heart block	3	3
Delay in conduction	5	2
Ventricular fibrillation	2	4

The Appraisal of Heart Affections*

S. CALVIN SMITH, M.S., M.D.,
Philadelphia

INTRODUCTION

There is some method in my having chosen as a title The Appraisal of Heart Affections. A field so broad gives me, in football parlance, an opportunity to kick around all over the lot, without confining myself to punting away at murmurs and blood pressure estimates—subjects in which life insurance companies are adept goal kickers. If I can lead you far afield from such practiced gymnastics, I might have a chance at the ball myself.

HEART AFFECTIONS VERSUS HEART DISEASE

We are discussing heart affections—not heart disease. There would be no use in discussing the latter. The term heart disease implies actual structural change in heart tissue,—change in valvular or muscular structure, probably both, coexisting with those signs of circulatory failure which a defective heart muscle would naturally induce. Such signs of circulatory failure embrace shortness of breath, pulmonary edema, cough, anasarca, swollen ankles, pulse volume abnormalities, pulse rhythm irregularities, heart enlargement, chest pains, congestion of skin surface and congestion of any organ within the body, as well as defective functioning of any part that happens to be deprived of an adequate blood supply because the pump is defective. It is a familiar picture and a well nigh hopeless one.

THE BEGINNING OF HEART DISEASE

Such an advanced heart wreck would of course never be brought before a medical examiner. And yet the wreckage had its simple beginning. Heart disease does not develop in a day or in a week—even syphilis, the notorious destroyer of hearts, usually smoulders along, as far as cardiocirculatory signs are concerned, until twelve or fifteen years have elapsed following the initial lesion; then it bursts into a consuming flame. Ordinary infections that are less virulent might never wreck the heart, were it not that the burden is added to and the affected heart eventually dragged down to circulatory inefficiency by such simple loads as insufficient periods of convalescence, excessive physical demands, emotional strain, intercurrent infections, focal absorption, malnutrition, endocrine disturbances and the weight of advancing years. As heart disease has its simple beginning, there must be a period in its early development when the heart merely protests against a load: these protests are not evidence of heart disease,—they are only evidences of heart affections. The history is vague, the symptoms are indefinite, the physical signs are inconstant and it becomes a problem, from an insurance viewpoint, to properly appraise a heart so affected.

DEPLETION OF NORMAL HEART RESERVE

There is a reason for our difficulty in appraising early heart affections. The borderline between heart normality and heart abnormality is so finely drawn that one merges into another quite without contrast, much as sunset merges into twilight. If any one of you healthy men were to run rapidly around two or three blocks, in all probability you would return with a congested face, superficial veins engorged, breathing short and hurried, pulse rapid and low in volume, the precordial impulse diffuse, a precordial thrill probably present, the systolic pressure reading would certainly be over 150, the second sound at the aortic area would be sharply accented and ringing in character and the odds are that we would have no difficulty in agreeing upon a murmur being present in your heart. Of course you are a healthy person, and these signs would abate in from two to five minutes. But if they persisted, the borderline between heart health and a heart affection would have been crossed.

HEART FATIGUE SIMULATING HEART DISEASE

There is virtually no difference between the physiological heart and circulatory reactions which attend excessive, unaccustomed exercise, and pathological physical signs which often cause the rejection of an applicant. Both indicate a drain on the reserve power of the heart. Such distinction as is made is merely one of judgment; for in exercise, the immediate exciting cause is known and the physical signs are selflimited and abate promptly; in the rejected applicant, the exciting cause is unknown and the physical signs are more or less continuous as long as the cause remains active.

FINDING SUPPLEMENTING INDETERMINATE SIGNS

Surely the borderline between heart normality and heart abnormality is finely drawn. Physical signs have led us astray in the past. A medical publisher, whose life had been spent with physicians and who recently passed on in the fulness of years at seventy-six, delighted in exhibiting his astounding murmur to all who would listen—and when the face of the medical man began to grow serious, the old codger would relate how he was rejected forty-six years ago for life insurance by the master medical minds of that day. So we should seek for something to corroborate our cardiophysical findings if we are to appraise a heart affection judiciously. Fortunately, we can find this confirmatory testimony nowadays in a study of the previous history and in a study of the mechanism of the heart beat. Let us briefly consider a few salient points in history and later take some notice of mechanical derangements of the heart beat, as shown clinically by the irregular pulse and as registered by the heart itself in the graphic heart records which embellish the pages of our medical magazines.

PREVIOUS DISEASES THAT MAY IMPAIR HEART

History plays a large part in the present day appraisal of heart affections. The object in searching the history is to determine whether the individual has ever had any of those diseases which are definitely

*Read before the Philadelphia Medical Examiners' Association, October 1, 1923.

known to affect the heart; for the heart may have been damaged during the course of the infectious disease, and the damage may not be revealed until many years later, when some excessive physical demand or infection precipitates a cardiac break. Diphtheria, for example, affects the heart in twenty-two per cent. of the persons whom it attacks, and the presence of diphtheria in the history of a patient would make one feel that the infection had some connection with later day heart symptoms, no matter how much time had elapsed between the infection and the heart symptoms. While scarlet fever affects the heart in only five per cent. of the persons attacked, the well known relation between scarlet fever and nephritis, which ensues at a later date, would make one feel that some long standing kidney involvement could be throwing a load upon the heart. Influenza is so frequently attended by heart muscle involvement, especially when there has been an insufficient period of convalescence, that the term post-influenzal myocarditis has a dreaded place in the medical vocabulary of today. Pneumonia is believed to affect the heart in ten per cent., and typhoid fever produces heart derangements in two per cent., of the persons affected.

THE TONSILLAR TRIO

The tonsillar trio, consisting of chorea, acute rheumatic fever and tonsillitis, have almost a selective affinity for heart tissue and all three have a great deal of weight in the appraisal of heart affections. It is surprising that the medical questionnaires of life insurance companies do not all inquire specifically into a history of tonsillitis. Figures recently compiled by the New York Heart Association show that the removal of tonsils prevented the recurrence of rheumatic fever in seventy-six per cent. and that the removal of tonsils prevented the recurrence of chorea in fifty per cent. of children previously affected with these diseases. The health credit of a person who has had repeated attacks of tonsillitis certainly stands upon slippery ground, for the well known relation between tonsillitis and acute rheumatic fever, plus statistics showing that the heart is damaged in twenty per cent. of the cases of acute rheumatic fever, makes tonsillitis a disease to be taken well into account by medical examiners.

When the diseases above referred to appear in the previous history of a person whose heart health is being considered, it is wise to assume that a heart defect is probably present. Not until every method of cardiac examination has been exhausted should the heart be considered as normal and regarded as absolved from participation in those diseases which are definitely known to affect many hearts.

CONCERNING HEART ENLARGEMENT

There is a point or two which we might touch upon in connection with the physical examination of an applicant, in order to bring out the advantages and disadvantages of certain clinical practices. One of these concerns the evidence of heart enlargement. I am not going to indulge in the usual trite remark that percussion of the heart is liable to error and hence inaccurate. As a matter of fact, the size of the heart can be very nicely approximated by percussion in the majority of instances and by most doctors. A good method of ascertaining the total transverse diameter is to percuss in the fourth interspace for the right border, beginning far to the right and coming toward the midsternal line. If there is no change in the percussion note and no change in the sense of resistance as one approaches the right sternocostal junction, it can be assumed that the right border of the heart occupies a normal position at the sternocostal junction. The left border of the heart can be determined far more accurately than the right, provided one percusses in the fifth interspace and takes as the left border that point where there is a change in note and an increased sense of resistance, together with the actual feeling of the pulsating organ beneath this point. X ray examination proves that the left border of the normal heart is at that point at which one can farthest feel the precordial impulse. Adding together the right and left distances from the midsternal line gives us the total transverse diameter of the heart.

Unfortunately, there is no such thing as a normal width for a heart. A heart that is eleven centimetres in its transverse diameter may be construed as heart enlargement in a slender, narrow chested person, while a transverse diameter of fourteen centimetres may be quite proportionate for a broad chested, heavy set iron worker. So we determine heart enlargement only by employing our sense of comparison and by deciding whether the heart width, as marked on the chest, is in relative proportion to the size of the thorax and the build of the individual.

SOURCES OF ERROR IN CARDIAC PERCUSSION

In estimating whether a heart is enlarged or not, it should be borne in mind that a heart does not necessarily need to enlarge in the transverse diameter. It is possible for a heart to enlarge in the anterior-posterior plane, and in such instances cardiac percussion is of course deceiving. Furthermore, heart enlargement is not an absolutely indispensable part of the picture of heart damage. A heart does not necessarily need to be enlarged to be defective. Small hearts can produce profound circulatory disturbance, without giving any evidence of ever having been enlarged.

VALUE OF EXERCISE TESTS

An exercise test is of definite value in appraising the heart. While of course we all subscribe to the platitude that no test has yet been devised to estimate the functional capacity of the heart, the fact still remains that a heart is not normal when, after exercise, hurried breathing and a rapid rate persist for several minutes. I have found such persistence to be due to paroxysms of auricular flutter, to nodal rhythm and to the sudden onset of transient auricular fibrillation, all three of which are such serious evidences of myocardial involvement. Acceptance of the applicant should be withheld until a systemic search has resulted in the detection of a probable and remediable cause for the disturbance. The normal hearts of young adults of military age return to the preexercise rate, and the respiration returns to the preexercise rate, within two minutes following such effort as hopping one hundred times on one foot. It is also of value to know that hearts which fail to respond to exercise with an increase in rate, especially when the respiratory rate is increased, are generally found to be abnormal hearts. Usually this sign is found in

persons whose cardiac reserve is depleted by battling with long continued, low grade infections, such as absorption from septic foci: sometimes, however, the pulse rate fails to respond to exercise for the reason that heart block is present.

SIGNIFICANCE OF THE ABNORMAL PULSE

From what has already been said, it is apparent that tachycardia in some instances is a physiological response of a well balanced heart to a stimulus; in other instances, tachycardia may mean that a toxic or degenerated area in heart tissue has assumed control of the heart rate.

In like manner, there are several other pulse abnormalities, some of which we know are totally without significance as far as cardiac pathology is concerned,—witness the irregularities called sinus arrhythmia and sinoauricular block. On the other hand, we encounter irregularities that are part or parcel of the picture of myocarditis,—such as auricular flutter, auricular fibrillation, heart block and ventricular alternation.

It is to the recently introduced methods of graphic heart examination that we owe our ability to differentiate the simpler pulse abnormalities from those of serious import. Furthermore, modern cardiology has elaborated a series of signs by which we can recognize the various types of intermittent pulse during clinical examination, without necessarily resorting to graphic heart study of every patient.

CONCLUSION

We will reserve for another occasion the consideration of the irregular pulse and the clinical value of graphic heart records. In closing, it may be said that the day is coming when life insurance companies, instead of rejecting applicants who exhibit heart irregularities, will accept certain applicants when the innocent nature of their irregularity is attested by graphic heart records which accompany the application. In addition to preventing the economic losses of the past, such records would be a definite protection, not only for the examining physician but also for the Chief Examiner's Office.

SUMMARY

The appraisal of heart affections can be rendered more accurate by applying the following points to the consideration of the case:—

1. A heart can be affected without necessarily being structurally diseased.
2. The reserve power of the heart can be exhausted in health or in disease, and in either circumstance the symptoms and signs bear a resemblance to each other.
3. Physical signs of heart affections should be supplemented by a search of the history and by cardiographic records before the heart is definitely condemned.
4. Tonsillar infectivity plays an important rôle in the production of heart affections.
5. Heart enlargement is not an indispensable part of the picture of heart disease. Small hearts can manifest profound symptoms of heart disturbance.
6. A heart is not normal when, after an exercise test, hurried breathing and a rapid rate persist for several minutes.
7. There are certain pulse irregularities that are not an evidence of heart disease, and graphic records that establish the physiological character of such irregularities are additional warrant for the acceptance of the applicant for insurance.
8. It is possible, by written heart records, to detect heart affections that cannot be recognized by any other means of examination. Thus electrocardiography is of importance in any life insurance or other examination in which a knowledge of the physical fitness of the individual is of first consideration.

Physiotherapy in Cardiovascular Disease

BASIL PARSONS-SMITH, M.D., M.R.C.P., Lond.,

London,

Physician to Out-Patients National Hospital for Diseases of the Heart, etc.

The subject of the treatment of disorders of the cardiovascular system by reeducation and physical methods is possessed of an importance which amply merits due appreciation by all who would endeavor to employ rational methods for the cure of circulatory derangements. During recent years advances of an important character have become developed which not only broaden our therapeutic limits, but incidentally prove that treatment may be entirely efficient in certain cases, without the intervention of drugs or medicinal aids of any kind.

An attempt to determine the particular types of heart condition suitable for treatment by physical methods, also the selection of an appropriate scheme for application in individual cases, will require thoughtful discrimination. At the same time it is satisfactory to reflect that our scope tends gradually to enlarge, and it is becoming increasingly patent that physiotherapy merits full consideration whenever we may be called upon to outline a scheme of treatment for some form of cardiovascular disorder.

The space at my disposal being strictly limited I do not propose to discuss the fundamental principles which guide our deliberations and assist our endeavors towards a remedial objective, but briefly to summarize certain of the types of condition which exemplify the results of physical therapy to the best advantage.

A vast amount of studying during recent years has been centred upon D. A. H., the effort syndrome of Lewis, and it is to this variety of cardiac debility that I would first allude. Many striking peculiarities serve to distinguish the condition, its symptoms and physical signs are clearly defined,

structural disease does not obtain, and the deficient response to effort may be taken to indicate impairment of neuromuscular control which, by reason of its profound implication, determines the exaggerated cardiovascular manifestations which typify the complaint.

During the progress of the recent war opportunities were presented for the study of D. A. H. upon a comparatively large scale; the etiology of the condition, which need not here detain us, embraced a large variety of widely differing causes, the treatment, moreover, which I propose to epitomize, was moderately uniform.

From the onset it became obvious that active methods and physical reeducation should be adopted as early as possible after the establishment of definite convalescence; graduated exercises were regarded as the backbone of the treatment. These were performed under the guidance of skilled and expert instructors, and supervised by a medical officer, who, being thoroughly versed in the detail and technic of the drill from the practical point of view, fully appreciated the effects of the individual exercises, also the difficulties, apparent or real, which the patients might from time to time experience.

It is unnecessary in the present context to set out in detail a list of the exercises which comprised the program of the classes; suffice it to say they were selected with care to include an extensive variety of simple movements of limbs and trunk in combination with breathing exercises and short intervals of rest; incidentally, to avoid monotony, certain games were introduced into the daily physical training table, the value of these latter depending not only upon the competitive stimulus which they inculcate but also upon the development of an improved coordination of brain and muscle response.

Improvement was carefully watched for by routine examinations of the objective phenomena, cardiovascular, respiratory and others, following the prescribed exercises, and an improved tolerance of the latter was considered sufficient indication for progress to the advanced grades of effort, and for the route marches of graded severity which supplemented the later stages of the course of treatment.

The results following the adoption of graduated exercises for the cure of D. A. H. in soldiers were of so uniformly satisfactory a character that we may have no hesitation in advising a similar but modified scheme of physical therapy for the treatment of functional derangements of the cardiovascular system which so frequently complicate and prejudice the convalescence from certain of the simple diseases which affect the civil population. Moreover it is abundantly proved that the treatment of such cases of cardiac instability by rest alone will be fraught with disaster, further that it will require nothing more than an ordinarily wise discretion to decide when the opportune moment has arrived for the initiation of the first stages of the active treatment.

Our aim being to restore the normal healthy balance that presides over the circulatory adjustments which are refined to meet the demands of rest and effort, we shall need to scrutinize most carefully the tolerance of exercise as exhibited by the patient during the course of the treatment, in order that we may be supplied with the necessary data for the gradation of the movements and exercises which, from the reeducation point of view, are now so wisely adopted. Improvement may be judged to some extent by a diminution in the intensity of the symptoms, but it is customary in practice to place more reliance on physical signs, the objective phenomena portrayed by the circulatory, respiratory, and other symptoms, and the general features which may be observed to characterize the facial aspect of the patient at the cessation of the remedial exercise. With regard, moreover, to the specific effects upon the circulatory mechanism it rapidly becomes obvious that the general circulation is improved as a result largely of a definite increase in the amplitude of the heart's contraction, and that incidentally the coronary vessels are more efficiently supplied, the heart's contraction being strengthened thereby; its nutrition being raised, and the elimination of waste products, both locally in the cardiac muscle also in the system generally, proceeding with augmented vigor.

The second variety of case to which I shall briefly refer is that exemplified by the patient who suffers from cardiac disturbances, pain, palpitation, irregularities (more especially premature contractions), dyspnea, etc., in association with gastric maladies, deficient secretion, and asthenic states, dilatation of the organ, and deficiency of its peristaltic movements; in other words I find that patients whose cardiac phenomena depend upon reflex causes, gastric in origin, are admirably suited to treatment by physical methods; these latter I propose to outline. First however, it is necessary for a moment to consider certain clinical factors; a variety of symptoms produce sensations of physical incapacity in grades which differ materially from case to case. The more common include circulatory commotions such as irregular beating of the heart, stoppage and palpitation which as a rule occur in relation to meals, and are aggravated by persistent flatulent distention. In addition there is a tendency to nervous prostration, irritability, depression, insomnia and syncopal attacks. The physical signs embrace a somewhat motley collection of abnormalities; of these two only need concern us in the present context, viz., irregularity of heart action, and dilatation of the stomach; the latter in its gradual development becomes a focus of extreme irritability, whence stimuli persistently ascend, lowering the threshold of reflex cardiac excitation, and incidentally permitting the passage of abnormal impulses to the heart which disturb its rhythm, and interfere with its functional capacity to such an extent as to cause objective signs and symptoms of a particularly distressing nature.

The diagnosis being established by a correct judgment of gastric cause and cardiac effect, it obviously follows that lines of treatment need offer no special difficulty; complete rest in bed, with fluid restriction and a minimum of food will be essential in all cases. In addition, however, to the beneficial effects of rest and starvation much permanent relief will be obtained by the prescription of daily lavage and abdominal massage; the latter should follow the former each morning for the first ten days in the treatment of a case of average severity and be continued later as necessary. It is my practice to con-

bine with the massage passive exercises and depletive movements of the extremities daily, and to replace the former by resistance movements as soon as possible, watching the exercise tolerance with care during the whole progress of the treatment. During the second week the diet may be amplified in combination with the prescription of a bitter stomachic, acids, pepsin or such like remedy, and, the convalescent stage having been reached, it will only remain to instruct the patient how best he may complete his cure and avoid a recurrence of the malady in the future. Dietary restrictions, regularity of daily routine, habits and customs, also the question of smoking, will need to be carefully considered; special emphasis must, however, be accorded to the matter of daily exercise which should be selected to suit the requirements of each individual case, and will obviously vary considerably, the more elderly patients confining themselves to gentle walking games such as croquet, billiards, and others, with occasional courses of massage and movements, the more vigorous adopting forms of muscular effort which require a higher degree of physical endurance, viz., golf, tennis, shooting, swimming, climbing, horseback riding, and other sports, which all, in themselves, combine the advantages and good effects of general energetic massage.

The third group of cases which I have selected for mention includes those patients whose malady centres round an abnormally elevated range of blood pressure. A moment's consideration will suffice to remind us of the extensive etiology of this condition, further that in certain instances, for example patients with senile or decrescent arteriosclerosis, the blood pressure is frequently raised as a conservative measure, and to attempt a reduction would be both unnecessary and inadvisable. In the absence, however, of gross organic disease and degeneration, certain patients are afflicted with the commonly accepted symptoms of high blood pressure, cerebral, cardiac, and otherwise, the whole process depending upon some such factor as an increased viscidity of the blood, excessive friction, or the interference of vasomotor spasm and narrowing of the arterial bed.

This somewhat special type of disease, designated by Clifford Allbutt as hyperpiesis is peculiarly suited to treatment by physical methods combined with adequate rest, efficient purgation, venesection, and dietary restrictions which need not here detain us. According to the age of the patient, his previous mode of life, and general physiological makeup, we shall select an appropriate line of physical therapy, endeavoring at all times to ensure an improved circulation through the great muscular areas, whether it be by means of active exercise in some form, walking, games, hill climbing, or the more passive methods such as massage, movements passive or resistant, sweat baths or warm packs, and high frequency currents which in favorable cases, lower the peripheral resistance (incidentally therefore the blood pressure), assist in the dissipation of toxic substances, and reduce the degree of blood viscosity.

Myocarditis

ERNST P. BOAS, M.D.,
New York,
Medical Director, Montefiore Hospital for Chronic Diseases

GENERAL CONSIDERATIONS

Myocarditis, both acute and chronic, is a much abused term. It is invoked whenever there are any symptoms or physical signs that might be interpreted as indicating myocardial weakness. Tachycardia, precordial pain and breathlessness following an acute infectious disease, signs and symptoms of an insufficient circulation in an older individual, weak or distant heart sounds, low blood pressure, are all too frequently attributed to myocarditis. It is not simply a stylistic purism to demand greater care and circumspection in the use of this term. A thorough understanding of the affections of the heart muscle requires a stricter definition, for words, incorrectly used, bring no clear concept to the mind. The term myocarditis should be confined to its etymological meaning, namely, an infection, acute or chronic, of the heart muscle. The other conditions which have been classified under this name should be assigned to different categories.

By far the most frequent type of myocarditis is that induced by the rheumatic virus. Next in frequency is chronic syphilitic inflammation of the heart muscle. Myocarditis may accompany or follow many of the acute infectious diseases, notably diphtheria, pneumonia, scarlet fever, typhoid and typhus fever and influenza. Rheumatic myocarditis is usually associated with endocarditis and pericarditis; syphilitic myocarditis with aortitis and disease of the aortic valve.

MYOCARDITIS

The diagnosis of myocarditis remains one of the most difficult problems in medicine, because of the fact that there are no pathognomonic signs of the disorder, and because the symptoms of disturbed muscular function are often obscured by accompanying signs dependent on disease of other parts of the circulatory apparatus.

Stokes (1) was probably the first to point out the physical signs indicating myocardial involvement in the course of acute infectious diseases. He described the weak first sound and the rapid pulse, and pointed out the grave significance of a change in rhythm or of embryocardia. He noted the flabbiness of the heart in these cases at postmortem. We may add to these signs dilatation of the heart and the appearance of gallop rhythm. A persistent fever, accompanied by a pulse rate more rapid than would be expected, is very suggestive, if no other cause for the fever can be discovered.

DIAGNOSIS

The diagnosis of myocarditis will rest in large part on the recognition of the nature of the underlying infection. If there are symptoms pointing to impairment of the heart muscle accompanying one of the rheumatic infections, diphtheria, or syphilis, the likelihood that the heart muscle shares in the general infection is very great. In the presence of the other infectious diseases, such as pneumonia, influenza, scarlet fever and typhoid fever, greater circumspection must be employed.

The most significant evidence of myocardial invasion is the appearance of an irregularity of the heart beat. This is not always easy to detect, but if carefully sought for, particularly with the employment of instrumental aids, such as the polygraph or electrocardiograph, will be found quite frequently. The arrhythmia may be caused by premature beats, by paroxysmal auricular fibrillation, or paroxysmal tachycardia. Partial heart block, which is particularly frequent in rheumatic fever and in diphtheria, can usually be recognized only in the graphic tracing by noting the prolonged auriculoventricular interval which normally does not exceed 0.2 seconds. Occasionally a dropped beat may be noted on auscultation, giving evidence of the complete blocking of an auricular impulse. Arborization block and bundle branch block are more uncommon manifestations. Syphilitic myocarditis too is often associated with some form of heart block.

In addition to the signs enumerated above, the patient usually presents signs of general infection, such as fever, prostration and leucocytosis. A rapidly appearing secondary anemia is seen with particular frequency in the rheumatic infections.

In those cases in which the course of the myocarditis is fulminating, as, for instance, in diphtheria, or, at times, in the rare cases of interstitial myocarditis, the patient may experience sudden extreme prostration or collapse, with vomiting. More often there are no definite localizing symptoms. An accompanying pericarditis or endocarditis may help in drawing attention to the heart, for both of these localizations are usually associated with myocardial involvement, particularly in the rheumatic cases. The congestive signs of heart failure, such as edema and hepatic enlargement, are not conspicuous in most cases of acute myocarditis.

VASOMOTOR DISORDERS

The circulatory insufficiency that accompanies the acute infectious diseases is due, by no means exclusively, to injury of the heart muscle by the bacterial toxins. Disordered function of the vasomotor centre, actual injury to the arteries and capillaries, or a disturbed nervous control of the heart, contribute largely to the symptoms of circulatory failure.

Naunyn (2) was among the first to point out that death in these patients is not always caused by failure of the heart, but that it may be conditioned by an atony of the bloodvessels due to a disordered vasomotor system. Romberg (3) and his students made an extensive experimental study of the circulatory failure in diphtheria and pneumonia, and were able to show that in many cases the heart remains functionally capable even after grave symptoms of circulatory failure have become manifest, provided the blood pressure is artificially elevated and an adequate amount of blood is returned to the heart from the periphery. They believe that the important and earliest injury is to the medullary vasomotor centre. With the fall in blood pressure the flow of blood through the coronary arteries becomes insufficient, and myocardial weakness, due both to the toxins of the disease and to poor nutrition of the heart muscle, sets in. MacCallum (4) has confirmed their work. Porter (5), on the other hand, has adduced evidence that the vasomotor centre is not impaired in diphtheria intoxication. That these disturbances may be caused by disordered function of the sympathetic ganglia is suggested by recent studies in which degenerative changes were found in the sympathetic ganglia of patients who had succumbed to acute infectious diseases (6). It is probable from more recent studies of capillary function that collapse and many of the graver circulatory disturbances accompanying the acute infections are due to injury and dilatation of the smallest arterioles and of the capillaries (7). This mechanism is similar to the one causing surgical shock.

NEUROCIRCULATORY ASTHENIA

Furthermore, the circulatory symptoms observed in convalescence from acute infectious disease are mainly due to malfunction of the peripheral vascular mechanism, possibly secondary to injury of some of the internal secretory glands, and are analogous in their character and origin to the symptoms of neurocirculatory asthenia. It has been pointed out elsewhere that in the majority of cases the disturbance is determined by a constitutional inadequacy of the circulatory apparatus and that intercurrent infections aggravate and bring to light symptoms that may have been minimal or latent (8). In other individuals who have been perfectly healthy, an acute infectious disease may be followed by the same symptoms. In these patients, however, in contrast to the constitutional type, the cardiovascular disorder usually clears up completely in from six months to two years.

The common cardiovascular symptoms following infectious diseases are palpitation, breathlessness, precordial pain, rapid heart beat, throbbing peripheral arteries and vasomotor disturbances, such as acrocyanosis. The subjective phenomena are usually in the foreground. In addition, the patient may present many other complaints, such as ready fatigability, nervousness, vertigo or fainting, sweating and insomnia. It becomes a matter of some moment to determine whether or not some persistent myocardial damage is responsible for the disordered circulation, or whether the cause lies in faulty cardiac innervation or vasomotor control, for in the former case, absolute bed rest is indicated and in the latter, careful physical reeducation. In the absence of cardiac irregularities, cyanosis of the lips, enlargement of the liver or edema, it may be assumed that within several weeks after the infectious disease the myocardium has been functionally restored, although it may not yet be capable of supporting excessive effort. The following case is a particularly severe one.

Case I.—During the epidemic of 1918, an American officer, aged twenty-four, was stricken with influenza, followed by a virulent bronchopneumonia,

which lasted about five weeks. He was greatly prostrated by his illness and during convalescence constantly complained of palpitation, precordial pain and inability to take a deep breath. His pulse rate while lying in bed was about 120. He perspired easily and had a definite tremor of the hands. He was kept at absolute rest for a month after the defervescence of the fever without any improvement in his symptoms. Except for the rapid pulse rate, there was no evidence of cardiac disease. He was then cautiously compelled to get out of bed and within one week was walking about freely. Although he felt stronger, he still complained of palpitation and breathlessness. For a year after that he was unable to undertake any severe effort and it was two years before he was restored to normal. During this whole period he gave no evidence of organic heart disease but presented all the earmarks of neurocirculatory asthenia.

The problem becomes still more difficult when a patient with existing organic heart disease is subjected to an acute infectious disease, although here too, with care, one can usually separate the symptoms of vasomotor instability and disturbed innervation from those due to myocardial weakness.

SUMMARY

To sum up, the diagnosis of myocarditis may be made only in the presence of one of the infections which is known to be associated with infection of the heart muscle, and when there are localizing signs such as cardiac dilatation or arrhythmia. Tachycardia, breathlessness, precordial pain, weak heart sounds and low blood pressure are of little diagnostic value in this connection. Very often these are caused by the vasomotor disturbances which so often follow acute infectious disease.

The term chronic myocarditis should be used only to describe a chronic infection of the heart muscle, such as syphilis, or very rarely, tuberculosis or actinomycosis. Myocardial degeneration consequent upon arteriosclerosis of the coronary arteries, or myocardial insufficiency following hypertension or pulmonary emphysema, are not inflammatory processes and should be sharply differentiated because their clinical course is quite different. The scarred heart muscle of a patient with long standing rheumatic heart disease is not a chronic myocarditis, but is the end result of previous attacks of acute or subacute myocarditis.

Exercise from the Cardiovascular Viewpoint*

A. E. RENNER, M.D.,
New York,
Assistant Attending Physician to Broad Street Hospital, Adjunct Attending Physician Central and Neurological Hospital, etc.

Analyzing the life of the average man, who in an ambitious way pursues a business that binds him to an office chair, or to a great extent forces him into sedentary habits, we find the following: He is very apt to indulge in recreative exercise to such an extent that in a short space of time, either a hurried hour at some gymnasium, or, perhaps, during a week-end, he attempts to exert too much energy; to put too many muscles into play, and that these efforts are of decided harm to his cardiovascular apparatus. He suffers because of his business drive methods, which make his athletics an "energy drive."

The impression widely prevalent today is, that bodily exercise must entail bodily strain, as evidenced by breathlessness, pumping heart action, profuse perspiration, more or less fatigue, and most of the other signs of kinetic drive or overstrain. Frequently such activities have not only caused serious strain of the heart and bloodvessels, but often sudden death in the gymnasium or on the athletic field has proved the extent of the damage that injudicious exertion can produce. The question of the benefits or injuries of exercise has been studied by medical men from practically every angle during the last fifty years. It is only recently, however, that a definite status of this most interesting problem is being established (1-9).

Ling, of Sweden, was the first to work out a system of massage and exercise, with the view of perfecting such bodily deficiencies as were amenable to this form of treatment. Such names as Traube and Stokes stand in the pioneer field of those who ventured to supplement rest and medication in heart disease with exercise. Zander, of Stockholm, advocated the use of his apparatus, not only for joint and muscle deformities, but also for circulatory diseases. Oertel even recommended carefully graded and supervised mountain climbing for the restoration and reconditioning of the heart muscle, and in many cases showed brilliant results. The Schott brothers, in addition to regulated gymnastics, advocated carbonic acid baths. It will be seen, therefore, that the previously held dictum which condemned every patient with heart disease to a life of inactivity or even total invalidism has gradually been discarded.

There is now a better knowledge of the factors

*Read before the New York Academy of Pathological Science, New York, January 26, 1923.

concerned in the maintenance of the circulation. Advances in the field of perfecting instrumental devices for studies of the mechanics and physics of cardiac activity, have added to the accuracy of study and observation. Blood pressure estimation, studies of the various phases of the cardiac cycle, rhythm interpretation, and a decidedly clearer understanding of the diseased heart with its abnormal functioning have made the problems clearer in a wide range.

The newer studies in cardiology have become almost universal in the last decade, and the various apparatus used in studying the heart are now commonly known. Why, then, this astounding high percentage of sudden deaths from heart failure, and the reprehensible figures of increasing numbers of cardiacs?

In the light of our better understanding of the factors governing heart work, heart power, these deaths are inexcusable, and must be attributed to carelessness. Deducting the factors of present day competition, control of our patients, the common practice of selfmedication, the sequelæ of major illnesses, there still remain the facts and figures of present day mortality statistics. These figures are interesting (10):

DEATH RATE IN 100,000 OF POPULATION, OCTOBER, 1922

Cerebral hemorrhage	55.7
Pneumonia (all forms)	40.4
Organic heart disease	104.2

COMPARISON OF CAUSES OF DEATH FOR FIRST TEN MONTHS OF 1921 AND 1922. ORDINARY BUSINESS OF FORTY-FOUR LIFE INSURANCE COMPANIES. NUMBER OF DEATHS AND DEATH RATES PER 100,000 EXPOSED.*

Causes of Death	First Ten Months 1921 No. of Deaths	First Ten Months 1921 Death Rate per 100,000	First Ten Months 1922 No. of Deaths	First Ten Months 1922 Death Rate per 100,000	Percentage 1922 of 1921 Death Rate
1. Typhoid fever	625	6.7	478	4.9	73.13
2. Influenza	608	6.6	1,527	15.7	237.88
3. Tuberculosis (all forms)	5,169	55.7	5,312	54.7	98.20
4. Cancer	5,476	59.0	5,753	59.2	100.34
5. Cerebral hemorrhage	4,465	48.1	4,542	46.8	97.30
6. Organic diseases of heart	7,732	83.3	8,723	89.8	107.80
7. Pneumonia—all forms.	4,085	44.0	4,839	49.8	113.18
8. Other respiratory diseases	818	8.8	719	7.4	84.09
9. Bright's disease	4,336	46.7	4,663	48.0	102.78
10. Puerperal state	420	4.5	409	4.2	93.33
11. Suicides	1,803	19.4	1,682	17.3	89.18
12. Homicides	550	5.9	480	4.9	83.05
13. Automobile accidents and injuries	1,029	11.1	1,076	11.1	.....
14. Other external causes	3,661	39.5	3,640	37.5	94.94
15. All other causes	19,197	206.9	18,195	187.4	90.58
16. Total—all causes	59,974	646.5	62,038	638.9	98.82
Years of life exposed to risk	9,277,402		9,710,360		

*The mortality experience included in this tabulation is based upon 83.15 per cent of the total number of ordinary policies in force December 31, 1921, in all American companies.

The medical advice given a patient, who because of obesity or for some other requirement shows the necessity for such a procedure, is, usually, "you need exercise," and in a general way the patient is left to his own devices. He seeks quite naturally to combine his exercises with the daily routine, or in many instances puts himself under the haphazard care of an athletic instructor, who, again in as general a way as the physician, recommends a course or series of exercises which are conceded to add to or diminish from the muscular development, height, weight, endurance, etc., of the participant.

In some gymnasia I have seen sphygmomanometers, stethoscopes, and other impressive paraphernalia displayed for the purpose of making a show of the care and safety with which patrons are selected for a specific course. In one such gymnasium, situated in the financial district and enjoying the patronage of prominent men, the socalled professor was of the opinion that excessive workouts were the only beneficial form of exercise, and his belief was enforced promiscuously! In another similarly situated gymnasium, the handball court was without windows or any other means of ventilation, being of necessity illuminated by electric lights. Such exertion, even though the mental effort is relieved in the form of competitive games, is of distinct harm to the man of forty or over, and especially so when it follows a period of sedentary inactivity.

Handball, tennis, basketball, jai-alai, track running, or, in short, such exertion as demands that the weight of the body be moved quickly and forcefully over a certain ground in a given time, are hardly suited to the capacities of the business man. After a week of indoor inactivity, suboxidation of muscle circulation, excessive diet, lack of bodily rest, bowel stasis, etc., the heart is in poor condition to withstand the strain of many pounds, often equalling several times the amount of the body weight.

The hopping test, for example, as used in the Army, wherein the soldier is made to hop one hundred times on one foot, gives the following amount of calculated work: A soldier, of the average weight of 150 pounds, hops one hundred times on one foot, thereby raising the toes about two inches from the ground and the knee about three inches. We reckon then the following equation: $150 \times 5/12$ (feet) $\times 100$, or over 6,000 foot pounds of energy (11). The heart, then, in so simple an exertion is capable of performing such heavy labor, and soon after, if the muscle is young and all other factors are equal, the circulatory concomitants, such as capillary flow and vessel dilatation, soon reestablish an even circulation.

It would be neglectful to ignore the stress and strain of present day civilization, which in their cumulative effect undoubtedly play a great part in the production of heart muscle degeneration and damage. Sooner or later, then, if an extreme demand is made upon such a heart, some sudden unaccustomed exertion, beyond its boundaries so to speak, the heart fails.

In 1912, an interesting controversy was begun around the question as to whether athletic training is dangerous. The origin of the debate was a paper written by the then Surgeon General of the Navy, in which he deplored the intensive training of the Annapolis cadet, and practically proved that athletic overwork, which could not be continued in sea service, had a decided influence on the after health of seamen.

Various instructors in the fields of athletics, both lay and professional, and representative of the largest universities in America, viewed such a radical condemnation from various angles. The *New York Times*, February 4, 1912, prints the diverse opinions of such men as Surgeon General Stokes, W. G. Anderson (Yale athletic supervisor and physician), Dr. Dudley H. Sargent, of the Hemonway Gymnasium, Harvard University, and others prominent in the athletic directions of the large colleges in this country. To be sure, the question was concerned with the ill effects of athletic training, yet most of the opinions were directed solely to football injuries.

preparatory training, diet, etc., ignoring entirely the broader question involved. Dr. Estes, physiologist of Lehigh University, who, because of his physiological reasoning, was perhaps better able to realize the main issues concerned in the mechanics of muscular energy, at that time discussed the question with a wisdom that can well stand today. He is quoted concerning cardiac dilatations or acute heart failure, in part, as follows: "Sometimes so severe or extensive that it at once terminates the usefulness of the youngster as an athlete, and requires months for proper recompensation." Dr. Dudley Sargent, of Harvard, advises against the competitive strain and tension in our various forms of college athletics to prevent the evils of overstraining and overtraining. If these ill results can follow exertion in the young, who are especially selected for the training table, how much more readily possible is overstrain and the end results of heart failure in the man of forty or fifty, whose body can much less withstand the trespass of the limits of cardiac capacity.

Systematic exercise or Army setting up exercises and the many means of mechanically stimulating the muscles to active or passive motion, all have a definite sphere. The vibration tables, pandiculation, Bante's, Schott, or Swedish resistance movements, all are beneficial in certain types of cases only. To use them in every case that seems to indicate obesity reduction, or energetic exercise, or to require the various factors associated with gymnastics, means that the patient is in as grave danger as though he were given promiscuous doses of a lethal drug.

To understand more fully the mechanics of the body as aroused by muscle exertion, it may be in place to review the motor physiology. The changes which occur are: 1. Circulatory (cardiac and vascular) primarily, and hemic secondarily. 2. Systemic or general changes. There is, of course, at once increased rate and force of the pulse. Increased velocity of blood flow, a more energetic and more complete distribution of the blood throughout the capillary bed and circulatory tree. The arteries and veins dilate to accommodate the increased blood volume, blood having left the organs and muscles in increasing amounts and is now in the circulatory stream (12).

Heart activity is increased to a proportionate degree depending upon the amount of exertion, the position of the body and other factors, i. e., rest period, conditions of respiration, presence of oxygen, etc. There is greater oxidation throughout the cells of the body, and there is a stimulation of the brain centres. The amplitude of the respirations increases, there is an increase in the blood pressure, both systolic and diastolic, which, in the normal individual, returns to average limits shortly after the exertion has ceased.

Such factors as previous rest, general fitness, overeating, overindulgence in tobacco or alcohol, coffee, etc., play a deterring rôle, not only in the condition of the athlete but in the effects, immediate and remote, of the exercise. Further signs of bodily activity are perspiration, which aids in the elimination of waste products and exhaust substances; increased intestinal peristalsis, because of the massage which the trunk muscles employ, and because of the action of gravity; increased secretion of all glands, because of the stimulus to the general circulation. The action on the muscle tissue itself is one of muscle fibre stimulation through its nerve endings and branches, and in consequence of the resulting increase in circulation, the muscle cells increase in size and eventually in number. Greater pliability to the whole body results, because of the greater metabolism of water in the muscles and their being accustomed to being used in various postures.

Therefore, it is evident that exercise in a general way is of decided and convincing benefit to the body, yet it is just on this apparently axiomatic principle that the danger is founded. To be sure, increased nutrition produces increased power of function, but from the cardiological viewpoint increased function may not be desired in a heart muscle that easily stretches and dilates, or which has not the tonicity to sustain itself during an exertion, no matter how slight.

The various functional tests that have for their aim the calculation of cardiac muscle value are not a reliable guide. To express this value in arithmetical equations, based on the factors of a certain weight, or, perhaps, a certain muscle group movement, does not take into consideration the other potent factors of cardiac vitality. Cardiac circulation, i. e., coronary arterial flow, controls, perhaps, most of the capacity of the heart's ability to do a certain work. Local metabolism within the heart also must be a considerable factor, as well as the forces included under the terms *vis a tergo* and *vis a fronto*. None of these units of cardiac physiology has as yet been measured in such a way as to be applicable according to a scale or rule to determine just how far the heart can exert itself.

Blood pressure readings, pulse increase comparisons, estimation of heart sounds, apical excursion, the occurrence of such signs as palpitation upon a given exercise, or, perhaps, the pain and dyspnea syndrome, do not offer the least dependable index of cardiac vital capacity.

SUMMARY.

1. There are at the present time no reliable functional capacity heart tests.

2. In prescribing exercise for the cardiac invalid, great caution at all times must be observed, and there should be capable supervision of such exercise.

3. No man in the fifth decade and beyond should be allowed athletics that require great energy unless he can be safeguarded against overexertion; and all exercise should be indulged in only when the conditions of the body vitality are favorable to it.

Digitalis Taken Continuously for Thirty-Six Years

Clinical Note

LOUIS FAUGERES BISHOP, M.D., Sc.D., F.A.C.P.,
New York,
Consultant in Heart and Blood Vessel Diseases, Lincoln Hospital

REPORT OF THE CASE

Mrs. B.I.L.I. came to me for a general appraisal of her heart condition and advice. She complained only of occasional slight dyspnea, but gave a remarkable history of heart disease and of having

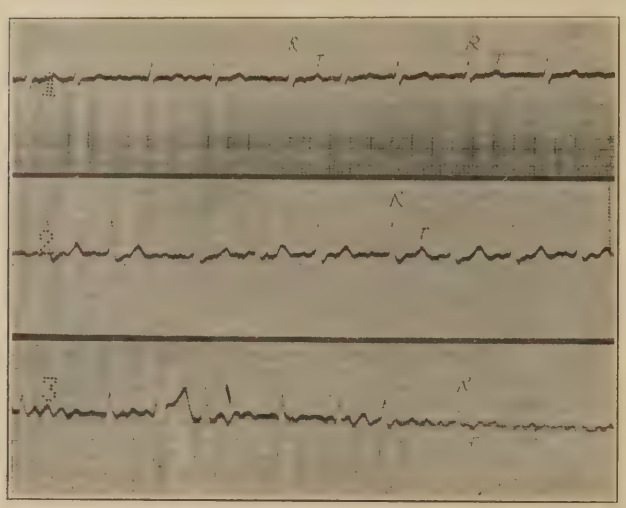

FIG. 1.—Electrocardiogram in a case of mitral stenosis with fibrillation giving a history of having used digitalis for thirty-six years.

taken digitalis continuously, almost daily, in regulated doses for thirty-six years.

At fourteen years of age she had typhoid fever and afterward was given digitalis in five drop doses, three times a day for a weak heart. About this time her pulse became irregular and ever since that time she has found it necessary to take digitalis in order that she may escape dyspnea and cardiac discomfort. She usually regulates the dose according to her feelings and seldom goes a day without taking some.

The accompanying x ray and electrocardiogram are typical of mitral stenosis with fibrillation. Note the straight sided heart of mitral stenosis and the general enlargement and moderate dilatation of the aorta which may have had origin in the general vascular involvement at the time of the typhoid fever.

The electrocardiogram shows absolute irregularity of the heart beat of fibrillation, with the usual absence of any definite P wave. The ventricular rate is about 90. In the third lead there is an extrasystole having its origin in the left ventricle. These are often seen in people who take digitalis.

The examination of the lungs, liver and spleen were negative. The pulse was irregular in force and rhythm and over the mitral area there was a loud rough presystolic murmur with a soft systolic murmur. Over the aortic region there was a soft systolic murmur. The blood pressure from extreme beats was 100 diastolic and 190 systolic, but most of the beats showed a lower systolic level.

The patient was advised that she was doing perfectly well and that she could continue to regulate her digitalis doses according to her need. Her own physician was congratulated on his wise management of the patient for so many years.

There are probably other records of people who have used digitalis for more than thirty-six years but I do not know of any.

A significant point concerning the value of this

FIG. 2.—Orthodiagram in a case of mitral stenosis and fibrillation giving a history of the use of digitalis for thirty-six years.

method of treatment is that during all this time the patient never had one serious attack of decompensation.

Unrecognized Fractures of the Skull in Infants and Children*

ALFRED W. POLLAK, M.D.,
New York,
Adjunct Pediatrist to the Hospital for Joint Diseases.

In looking through the literature, little is found about fractures of the skull in infants or small children; it being apparently taken for granted, that either the bones of babies' skulls are too soft and pliable to receive a fracture, or that the injury is so severe that it causes a depression with injury to the brain, thereby causing the usual symptoms as they occur in the adult. The greater number of cases of fractured skulls, with severe symptoms or death, are fractures of the base of the skull, while the unrecognized fractures, to which I wish to call attention, are usually those of the cranial vault.

Most fractures of the base are *contre coup* fractures, which will be explained later. The skulls of infants are elastic and with their close fitting integuments predispose to little displacement of the bones, and only where there is a sharp or circumscribed blow, does a depressed fracture result. Scudder observes that in infants there are large areas of fibrous tissue between the skull bones which prevent the transmission of force to the base of the skull from the vertex, hence basal fractures are rather unusual. Owing to the infrequent displacement of the fragments, healing is often very rapid and in fractures of the vault, the fracture may not be demonstrable by x ray after the lapse of a few weeks.

Visibility by x ray of the fracture at some time after the injury, is directly proportional to the amount of deformity and the malalignment of the fragments.

Every child during infancy or childhood has fallen on or was struck on the head. In most instances there were no bad results or even marked symptoms, and the injury was passed over without further comment. Many of these children undoubtedly received fractures of the skull and recovered without other symptoms than those of mild shock. These cases were classified as mild concussion, "shook up brain," or "bad bump." If there are no major symptoms of depression or hemorrhage accompanying the fracture, the diagnosis is often overlooked. But is it not possible, that the skull being fractured, without depression, brain injury or pressure symptoms, and with the remaining localized mild meningitis, that occurs in some cases, may in later years cause one of the many brain disorders which have thus far been unaccounted for as to their origin.

Baetjer and Waters (1) suggest that in all injuries to the head an x ray should be taken, and if this were systematically done, the recorded percentage of fractures of the skull would be materially increased. Severe injury to other parts of the body has caused the brain symptoms to be overlooked and the condition diagnosed as shock, hysteria, or nervousness.

Fractures of the vault, in infants and children, are usually the result of direct violence, the force being applied, where the patient has fallen upon the skull. If no depression results, the fracture may be of the green stick, fissured, or comminuted variety. The comminuted variety is usually less extensive than the green stick or fissured fracture so far as lines of cleavage are concerned. Fractures of the vertex may involve either one or both tables but usually the latter as the diploe is absent in infants (2). The lines of fracture visible on the outside of the skull are seldom an index of what may be found upon its inner surface.

Fracture by *contre coup,* in which the violence is transmitted by the arched construction of the skull, to an area more or less distant from the point of contact, is frequently met with. A peculiarity of this form of fracture is that it is never depressed.

Doubtless many cases of concussion of the brain following head injury are accompanied by some fissuring of one or both tables. Fractures of the base are more commonly noted, as they give more definite symptoms of skull injury. The base is more readily fractured as it is nearly flat and is weakened by the large foramen magnum and the other numerous foramina. It is also very thin, being translucent in some portions. The base is protected by the structures of the neck below and by its great mobility upon the cervical vertebrae. The brain is also protected by a layer of cerebrospinal fluid between

*Read before the Clinical Society of the Hospital for Joint Diseases, November 14, 1922.

it and the base upon which the brain rests as on a water bed. The only place where the brain actually touches the base is where the under surface of the anterior lobes of the cerebrum rests upon the orbital plates of the frontal bone.

Nancrede has called attention to wounds caused by the passing of a small pointed instrument through the retrotarsal conjunctival fold, then penetrating the orbital roof leaving very little trace of injury, especially in children. A blow upon the nose may fracture the ethmoid bone and drive it upward against the brain. A blow or fall upon the chin may drive the condyle of the lower maxilla through the glenoid fossa.

Fairchild (3) gave the following conclusions. Violence of no great intensity applied to a limited skull area, may cause, 1, an injury with only temporary displacement, with rupture of a meningeal artery, without fracture; 2, fracture, without displacement or hemorrhage but causing pressure irritation and sclerosis; 3, scars, adhesions, cysts.

A better classification is as follows:

A.—Fractures of the vault.
1. Fracture of external table without fracture of internal table.
2. Fracture (slight) of external table with comminuted fracture of internal table.
3. Green stick fracture; bent external table and fractured internal table.
4. Linear or fissured fracture.
5. Depressed fracture.
6. Contrecoup fracture.
7 Perforating fracture.

B.—Fractures of the base.
1. Without injury to the brain.
2. With injury to the brain.

This classification is self explanatory but requires the following comment.

FRACTURES OF THE VAULT

1. Fractures of the external table without fracture of the internal are seen in cases of glancing blows, glancing bullets (gutter fracture), where the external table is "just chipped off."

2. Slight fracture of external table with comminuted fracture of internal table is usually included under the linear or fissured fractures.

3. Green stick fractures are those where the external table is dented in and the elasticity of the bone often permits it to rebound at once to its normal shape. This may or may not be accompanied by a fracture of the internal table. These fractures give no symptoms unless there is an accompanying hemorrhage. Birth injuries are usually of this type.

4, 5. Linear and fissured fractures are characterized by the cracking of both external and internal tables, the latter as a rule being more broken up than the external. Unless one of the splinters of bone projects into the dura or meningeal arteries, causing hemorrhage, they are, as a rule, not recognized. Depressed fractures are caused by the applied force being continued, thereby driving the fragments inward and injuring the dura and brain, with or without definite symptoms.

6. *Contre coup* fractures are usually of the base. The point of trauma is opposite or at a distance from the point of fracture, due to the elasticity of the cranial bones as a whole, with the greatest point of force opposite to the point of trauma. Cases have been reported where a blow on one side of the head fractured the bone on the opposite side, without injury to the base.

7. Perforating fractures are usually the result of explosions and are rarely seen in infants. Many cases (especially in adults) have been reported of very serious perforations of the skull, with loss of brain substance, where there were few, if any, symptoms, except the immediate shock.

FRACTURES OF THE BASE

While less frequent in children than in adults, fractures of the base of the skull are much more dangerous and usually give symptoms. The most common site of fracture is through the middle fossa, breaking the petrous portion of the temporal bone at its weakest part, i. e., in the neighborhood of the middle ear, and from this point fissures may extend in any direction. These are the most common and most dangerous. Fractures of the posterior fossa are often overlooked in the absence of symptoms and may only be found at postmortem examinations. Fractures of the anterior fossa usually give symptoms but occasionally a case is seen with few or no immediate signs.

Fractures of the skull, unless the fractured portion of the inner table causes symptoms of cerebral irritation, or unless there are signs of compression by coexisting hemorrhage, will not be recognized unless an x ray picture is taken. In the x ray pictures linear fractures are often confused with grooves of vessels. Stereoscopics should be used for differentiation. Fractures of the skull are usually diagnosed by the symptoms of injury to the underlying brain with its coverings, vessels and nerves, except in cases where there is an obvious depression of the skull or bleeding from the ear, nose, or subconjunctival hemorrhage.

Harte (4) observes that an uncomplicated fracture of the bones of the vertex is not any more serious than that of any of the flat bones. The danger is injury to the parts beneath. The consensus of opinion is that in fractures of the base the mortality is from thirty to forty-five per cent. Death from vault fractures is about twenty per cent. It is lowest in children due to the fact that many are of the so called green stick variety.

TREATMENT

The treatment of skull and brain injuries belongs to the surgeon. If there are no symptoms of depression or of brain injury, expectant treatment is the course to pursue. If there is evidence of depression or pressure on the brain, immediate surgical treatment should be resorted to. Communited vault fractures should have a thorough exploration. All fragments should be removed. Replacing fragments is frequently employed.

We may classify the aftereffects as follows:

1. Most fractures without depression become absolutely well.

2. Cases of mild concussion with loss of consciousness for a few seconds, often show subsequent changes in disposition.

3. Chronic headaches, usually of a constant dull aching type.

4. Inability to stand high temperatures.

5. Epilepsy, due to irritation, produced by bony spicules from depressed internal table, with blood effusion, resulting in thickening of the meninges and the formation of cysts, either beneath the site of the injury or on the opposite side.

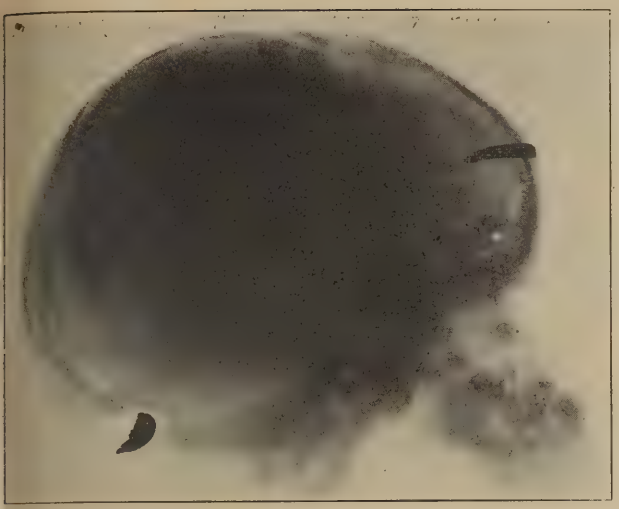

Fig. 1.—Case I. Fracture extending from the vertex downward and forward through the parietal frontal bone to the edge of the orbit; comminuted fragments at the apex.

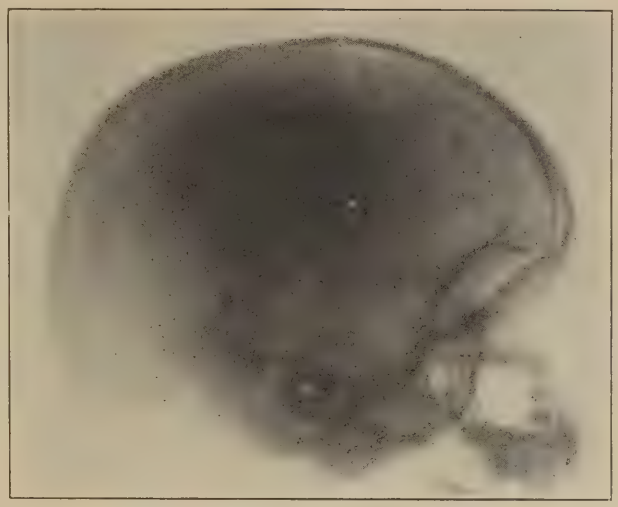

Fig. 2.—Case II. Extensive stellate fracture of the frontoparietal region, left side of cranial vault and a longitudinal fracture in the posterior fossa on the left side.

The following are the histories of a few cases, in which fractures of the skull were overlooked.

Case I.—A. S., aged three and one half, was a normal, intelligent child before the accident. On April 8, 1922, he fell or was thrown into a cellar from sidewalk, picked up unconscious, bleeding from right nostril, head and face bruised, was taken to a drug store, where cold applications to nose stopped bleeding. Two days later face became swollen and right hand and forearm became painful and swollen, was taken to a hospital, vomited several times, two days later fever developed. The physician at the hospital said, "it was a cold and bruises but no fracture." Next day x ray of forearm with negative report. The following day diphtheria developed and the patient was removed to a hospital for contagious diseases. Was there for four and a half weeks, in a poor condition, but sent home as physician thought the child would do better at home. The child had no appetite, was restless, had insomnia. Two days later the patient was taken back to the hospital where he was examined but nothing found. The patient was referred to the Hospital for Joint Diseases on June 23, 1922. Blood examination: Hemoglobin 62 per cent., red blood cells 4,048,000, white blood cells 7,200, Wassermann negative, eye examination negative, neurological examination negative, speech somewhat worse than before accident, confused at times, and did not walk as well as before. X ray showed arthritis of right elbow and wrist, atrophy and absorption of carpal bones. Synovitis of left elbow. X ray of skull showed an oblique fracture, extending from the vertex of the skull downwards and forwards through the parietal and frontal bones to the edge of the orbit; comminuted fragments at the vertex. Large V shaped fragment. No evidence of depression.

Fig. 3.—Case IV. Stellate fracture on right side of frontal bone.

Case II.—A. G., aged five. Two months before the examination the child fell through a coal hole, striking the back of its head, also receiving lacerated wound over right patella. The child was unconscious and had mild convulsions for ten minutes, bled from nose and vomited. Since the accident child had been very nervous and wet the bed; also suffered from occipital headache with stiffness of the neck and tenderness over the occipital region. For several days after the accident the child had fever and limped due to the injury to the knee. Present examination showed stiffness of the neck and tenderness over the occipital region and the child still complained of headache. The fundi were negative and reflexes were normal. Neurological examination was negative but the child has had tetanic attacks since the accident. X ray showed extensive stellate fracture of the frontoparietal region, left side of cranial vault, and a longitudinal fracture in the posterior fossa on the left side. No evidence of depression.

Case III.—H. T. E., aged two and a half. Occiput presentation at birth, noninstrumental delivery. At the age of three months it was noticed that the child held right upper extremity more limply than left but there seemed to be no paralysis. When the child was nine months old it was noticed that he used the left hand instead of the right and also held his head backwards and towards the

left. There were no convulsions. A diagnosis of right hemiplegia was made by a pediatrist and the child was referred to the Hospital for Joint Diseases, for massage and electricity. Routine examination showed a mentally backward child that could not walk without aid. The child was microcephalic and suffered from a birth hemiplegia. The Wassermann was negative. X ray showed a fracture of the middle fossa, on the left side, with distinct separation at the line of fracture. Also a fracture of the condyle of the left mandible with deformity was discovered. After the x ray diagnosis was made the mother recalled that at the age of six months the baby fell from a high chair, falling upon his head and nose. The nose, forehead and face on the left side became swollen and there was a marked decrease in the movements of the right upper extremity.

Case IV.—G. L., aged six. At the age of six months child fell out of bed striking head in the right frontal region. Nothing was thought of his accident at the time. The child was brought to me because it was badly behaved, wild and uncontrollable. X ray revealed a stellate fracture on the right side of the frontal bone. There was no depression. The fracture lines were faint in character apparently due to the fact that the fracture was of several years' standing.

Case V.—S. W., aged six and a half. This child was run over by a laundry wagon, the wheels passing over the pelvis. There was no loss of consciousness. Immediate examination showed bleeding from the vagina and urethra and an abrasion of the right thigh. Stellate fractures of the vault of the skull running into both temporal regions were shown by x ray examination. Fracture of the pelvis was also demonstrated. There had been no symptoms of fracture of the skull at any time, and this was shown only by x ray examination.

SUMMARY

The immediate symptoms in these cases when of sufficient importance to be noted at the time of the injury were due to meningeal irritation and congestion or to concussion of the brain. As the pathology of concussion is now conceded to be the rupture of brain capillaries, we may get the symptoms from very slight hemorrhages which are gradually absorbed and the symptoms relieved. Many of the obscure brain conditions of later life may have their origin in mild degrees of concussion. Therefore a guarded prognosis should always be given.

In conclusion, I would suggest that in every case where a child has fallen on or been struck upon the head, an x ray examination of the skull should be made and a careful history should be taken in order that no fracture of the skull should be overlooked.

I wish to acknowledge my indebtedness to Dr. Henry W. Frauenthal, surgeon in chief of the Hospital for Joint Diseases, for the privilege of observing and reporting these cases.

Postdiphtheritic Paralysis*

ALAN G. TERRELL, M.D.,
and DAVID H. HALLOCK, M.D.,
Southampton, N. Y.

In combating diphtheria physicians have to deal with one of the most insidious diseases that is prevalent today. This insidiousness exists because of the absence of marked symptoms of onset which, if present, would make an early diagnosis possible. It also exists because of the frequent similarity of the disease in its early stages to a simple attack of acute tonsillitis. Many patients are doomed before they are brought to the attention of the physician. Another factor which often lessens the patient's chance of recovery is the belief that a positive throat culture must be obtained before the diagnosis can be made and antitoxin administered. What chance has a patient, especially a child, if there is a delay of a day or two before it is decided that the trouble is in the throat, and then if there is a further procrastination of forty-eight hours or more before administering antitoxin, while awaiting the culture report? Very little indeed!

Again and again the State Department of Health has advised to give antitoxin first in a suspicious case and make the diagnosis afterward. Only by this method will the present mortality of this disease be further lowered. Why is it that the sporadic cases and the first cases in an epidemic are likely to be the fatal ones? Because these patients do not get the benefit of immediate specific treatment which others receive after the presence of the epidemic is fully recognized.

A negative throat culture may mean nothing. Any throat presenting a membrane of any description may be diphtheritic, especially if areas other than the tonsils are involved. It is astonishing how many cases one may see which yield rapidly to antitoxin and yet give a negative throat culture. Some of these may be cases of Vincent's angina or septic sore throat with a streptococcus membrane but strangely, in the latter too diphtheria antitoxin seems to have a beneficial effect.

The purpose of this article, in addition to sounding a warning note against procrastination in the treatment of diphtheria, is to present specific example of one of the late, and often most serious complication of this disease, namely death from postdiphtheritic paralysis.

*From the Medical Service of the Southampton Hospital, Southampton, N. Y. Read at the meeting of the Hampton Clinical Society, July 24, 1923.

Elsewhere (1) one of the writers has reported complete recovery from a general postdiphtheritic paralysis, of an adult who received no antitoxin. Unfortunately such a favorable outcome is uncertain; a fatal outcome is often present even in such cases as have received antitoxin two or three days after onset. Early treatment with sufficient dose would make this late complication almost unknown.

Paralysis is more a sequel than a complication. Its onset is usually during the second or third week of convalescence, at a time when one would think that recovery was assured. It is more frequent in adults than in children. Of 494 cases referred to by Osler, ninety-one died. The parts affected in their order of frequency are the muscles of the palate, pharynx, eye muscles, legs, arms, with the loss of reflexes inherent in each. Often the onset begins with one of the above paralyses and progresses gradually until heart and respiration alone remain active. Death may be due to aspiration pneumonia, starvation or paralysis of muscles of heart or respiration.

CASE REPORTS

The first case is an echo from the dark ages of medicine. In spite of the details herein related the family physician believes to this day that the disease was not diphtheria and the health authorities in the state in which the tragedy had its inception still assert that the negative throat cultures rule out the disease.

Case I.—M. P., aged three and one half years, female, children's ward, Hosp. No. 6841. Admitted July 26, 1922, died July 29, 1922. The chief complaint was weakness of the legs.

In March, 1922, two months before the present illness, the patient's infant brother, aged two months, was operated upon in a city outside New York State, by the family doctor for "tongue-tie." Two days later the wound became covered with a white membrane, followed by swelling of the tongue and a rapid spreading of the membrane. There was a foul odor to the breath, foul smelling mucosanguineous nasal discharge and swelling of the cervical nodes. The tongue became a white mass. No cultures were taken. This child recovered. No prophylactic doses of antitoxin were given to the other members of the family either at this or any other time.

One week later the mother's throat became sore and was treated for tonsillitis. Throat cultures were negative for Klebs-Loeffler bacilli. The mother recovered. She experienced some numbness and tingling of the extremities during convalescence.

The third week in March the throat of one sister became sore, as had the mother's, accompanied by profuse bloody foul smelling nasal discharge. Seven different cultures were pronounced negative by two different laboratories. Four days later six thousand units of antitoxin were given. This child died.

One week later the father was similarly affected with a sore throat. This was also cultured and a negative report rendered from the laboratory. A foul smelling, thick membrane covered the palate. The patient was in bed four days. He received no antitoxin. On the ninth day the heels became tender so that walking was painful. Red spots appeared on the inner aspect of the calves of the legs, lasting one week. The feet were considerably swollen and remained so for three weeks. The father recovered completely.

There were no similar cases at this time in the city nor had there been for a long time previously. The nursemaid was proved by three cultures to be no carrier. Schick tests were refused by the family. During these occurrences the patient was absent in another locality and perfectly well. The past history was negative.

The patient, M. P., returned home to the family in June, 1923. On June 11th she also acquired a sore throat similar to those described above with membrane formation. The breath was fetid. The membrane covered the tonsils and pillars. Throat cultures were also negative. On the third day, although throat culture was negative three thousand units of diphtheria antitoxin were given. The throat condition immediately began to improve, the membrane curling up and coming off in patches. There was slight laryngeal paralysis at this time. On the sixth day the child was out of bed, part of the time. However weakness of the palatal reflexes soon appeared, improved for a time, then became notably worse. On the eighteenth day the patient was well enough to travel and came to Long Island. After a month it was noticed that the child could not walk normally, stumbling on attempts to run. She then was admitted to the hospital for treatment of the paralysis.

The patient, a girl, was lying in bed, moving restlessly and tossing about. Her mind was clear; she answered questions, but with considerable speech defect, as if unable to form certain sounds. There was no evidence of somnolence. The pupils were equal, reacting readily to light and in accommodation. There was a ptosis of both lids, more marked on the right, and an internal strabismus of the right eye, ocular fundi were normal. There was no rigidity of the neck. The lungs were negative. The heart rate was rapid, sounds weak, rhythm regular, no adventitious sounds, pulse regular but weak.

There was marked weakness of all muscles of the extremities most noticed in distal portions, although all motions could be made. No elbow, wrist, patella, nor Achilles jerks were obtainable. The Babinski was negative, Kernig negative. A diagnosis of postdiphtheritic paralysis was made. After admission all findings noted above became more marked. Saliva collected in the throat and mouth and drooled out. The extremities soon became totally paralyzed. On July 29th the patient died of respiratory paralysis. Before admission treatment had consisted of strychnine sulphate, 1/100 grain by hypodermic three times daily, with massage twice a week. Upon admission massage was discontinued. Digitalis was given by hypodermic when the pulse became weak. During the last day nourishment was given by gavage.

Case II.—M. S., aged twenty-one, female ward, Hosp. No. 7410. Admitted, May 5, 1923, died May 5, 1923. The chief complaint was paralysis. The family history was negative. On March 15, 1923, the patient left Chicago, breaking quarantine, where her brother had died of a disease unquestionably diphtheria. She proceeded to her home on Long Island with two children. One of these two children

had been ill with a sore throat in Chicago, received diphtheria antitoxin and recovered. The other child reached home with a sort throat resembling follicular tonsillitis but culture proved the disease to be diphtheria. Antitoxin brought a prompt recovery. All other members of the family except the patient received a prophylactic dose of antitoxin and remained well.

Two weeks later after her return home a sore throat developed which simulated acute tonsillitis for forty-eight hours when a dense membrane developed with pronounced edema of the pharyngeal walls. Twenty thousand units of antitoxin were at once administered following the appearance of the membrane. Cultures were positive. The membrane disappeared in thirty-six hours, the edema in forty-eight hours. Five weeks later paralysis of the palatal muscles developed, followed by laryngeal paralysis, and later by paralysis of the muscles of deglutition, then of the face, arms and legs, in progression. On May 2nd hospital care was sought.

The patient was robust, well nourished, and well developed, suffering from great physical weakness, very pale but not cyanosed. The pupils were equal, reacted to light and accommodation, slight ptosis of both lids. There was weakness of facial muscles, paralysis of palatal muscles. All fluids taken were regurgitated through the nose. The patient was able to swallow salvia. The muscles of the larynx were partially paralyzed, voice husky with nasal twang. Effort of talking brought on coughing and dyspnea. The heart sounds were weak, rate 120, regular, no murmurs. The patient was unable to rise, walk or feed self. Flexion and extension were possible but very difficult. Flexion of fingers was impossible. Reflexes were universally diminished or absent.

On admission the patient was mentally clear, of good color and slightly nauseated. Five hours after admission sudden cyanosis of the extremities developed, which the patient noticed and exclaimed "I am dying, see how dark my hands are," and immediately fell back dead. The immediate cause of death was evidently paralysis of the heart, as the circulation first failed.

CONCLUSION

From the consideration of these two cases we wish to stress the following points:

1. Any throat membrane may be diphtheritic.
2. Give antitoxin first and then await the result of the throat culture. A negative report may mean nothing.
3. Immunize all contacts at once.

If these facts are carried in mind and acted upon it will be possible to still further reduce the morbidity and mortality of this treacherous disease.

Juvenile Tabes Dorsalis with Destruction of Hips from Charcot's Disease*

WALTER G. ELMER, M.D.,
Philadelphia,
Associate Professor of Orthopedic Surgery, Graduate School of Medicine, University of Pennsylvania

This patient is now eighteen years of age. When she was fourteen, while doing gymnastic exercises, she dislocated—or thought she had dislocated—her right hip. Later on, she was able to walk and run, her hip remaining out of place. She had pain which extended down her limb to her foot. She walked with a limp because of the shortening. She received chiropractic treatment. Later she was operated upon by a prominent orthopedic surgeon who removed the débris of the hip joint which had been destroyed. This was followed by drainage for twenty-two weeks. She wore a brace and a high shoe on the affected side to make up for the shortening. Injections of neosalvarsan were begun at this time. She has been treated in several hospitals since then and at a sanitarium at the seashore.

I first examined her in May, 1921. Her right lower limb was two and three quarter inches shorter than the left. The thigh could be flexed above a right angle, and in all other directions the range of movement was normal. The upper extremity of the femur was dislocated upward and moved freely about on the innominate bone. There was about two inches of free play upward and downward. Swelling and fluctuation indicated the presence of a large amount of fluid about the hip. The knee reflexes were absent. The pupils did not react to light. The x ray picture showed complete destruction of the head and neck of the femur with an upward dislocation of the shaft. The acetabulum had almost melted away. Up to this time she had received over fifty injections of neosalvarsan. The temperature range was from 98° to 102° and the pulse from 88 to 130. Weekly injections of neosalvarsan were given.

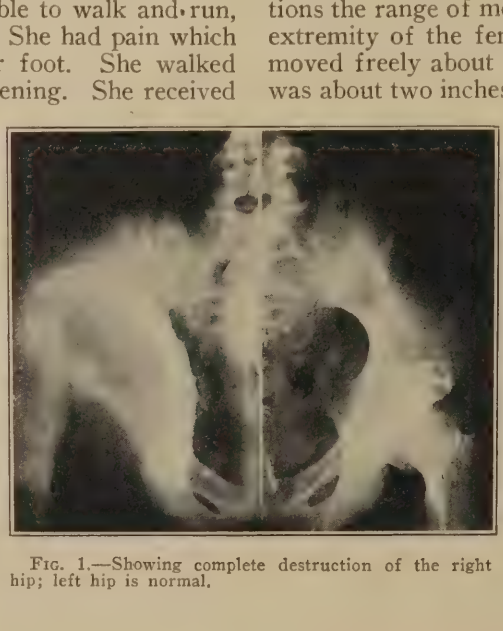

Fig. 1.—Showing complete destruction of the right hip; left hip is normal.

*Read before the College of Physicians of Philadelphia, January 2, 1923.

Two and a half months later the patient had improved in every way. She had a good color, had gained in weight, the fluid about the hip had been absorbed. She was provided with a brace with a padded ring so that her weight was borne by the tuberosity of the ischium and none by the hip.

She could walk without crutches. The temperature by this time remained about normal although the pulse rate was rather rapid.

The patient returned to her home August 9, 1921. She was again admitted for hospital treatment in November, 1922. Her general condition was very satisfactory. She was in good health, temperature and pulse normal, no fluid about the hip, very little free play upward and downward of the femur upon the ilium. It required a three inch block under the right foot to square the pelvis and straighten the spine. Injections of neosalvarsan were given.

Up to this time x ray pictures of the left hip had revealed nothing abnormal.

On the day that she was to leave the hospital she slipped while standing beside her bed but managed to fall over upon the bed instead of falling to the floor. She told me about this, fearing she might have injured her left hip. I examined her left hip as she lay supine upon the bed. The range of movement was free and normal in all directions, no crepitus, no pain and I assured her the hip was uninjured. She left the hospital that afternoon.

On reaching home, she climbed three flights of stairs and suddenly felt her left hip give way. I saw her at her home three days later—December 2, 1922. She had pain in her left hip and could not bear her weight upon it. There were marked tenderness and swelling about the hip and bone crepitus on motion. A diagnosis of fracture of the neck of the femur was made.

Fig. 2.—Showing the left hip still normal in June, 1921.

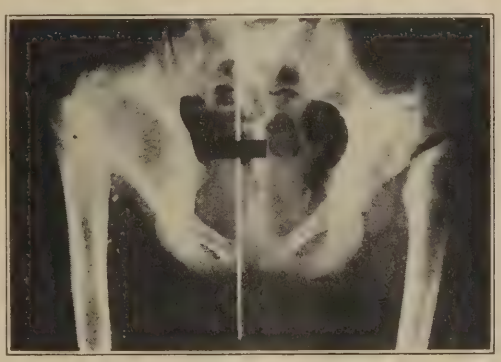

Fig. 3.—Showing that the left hip is following exactly the same course as the right.

She was readmitted to the hospital. Temperature 102°. Buck's Extension applied. Aspirated fluid was sterile. X ray pictures confirmed the diagnosis: that is—pathological intracapsular fracture of the neck of the femur due to the onset of Charcot's disease. The hip was immobilized in plaster of Paris from the toes to the thorax, another course of neosalvarsan was given, the temperature and pulse became normal, the fluid about the hip was absorbed.

January 22, 1923, the plaster cast was removed and braces put on. The patient then began to walk with crutches, no weight falling upon the hips but entirely upon the tuber ischii. She went to the seaside April 2, 1923.

October 22, 1923, she was again admitted to the hospital for examination. The x ray picture showed the upward dislocation of the shaft of the left femur and a considerable portion of the head of the femur still remaining. The destruction of the acetabulum was following much the same course as in the right hip.

The patient had discarded her braces of her own accord in July and was walking with crutches. I had intended to protect her hips from weight bearing for a long time—that is, long enough to permit dense fibrous connective tissue to firmly imbed the upper extremity of each femur upon the innominate bone, thus providing her with useful hip joints. Temperature and pulse were normal, she had gained in weight; her general health was excellent, no evidence of fluid about either hip; she was learning to walk a little—rather unsteadily—without her crutches; she had no pain.

The absence of the patellar reflexes, the Argyll-Robertson pupil and Romberg's symptom were clear indications that the earlier diagnosis of tabes dorsalis should remain unchanged.

The patient's attitude as she stands or walks is almost identical with that of double congenital dislocation of the hip. There is the marked lordosis and the prominence of each femoral extremity as it lies upon the dorsum of the ilium.

This girl is mentally normal, her intelligence if anything is rather above the average. She has a cheerful and happy disposition and has always been a favorite among the other patients in the hospital ward.

A series of Wassermann examinations was carried out from the time the patient first came under our care to the present time and the only items of importance are as follows:

On November 16, 1922, the blood Wassermann was negative, the spinal fluid strongly positive, globulin negative, cells three per c. mm. On October 19, 1923, blood Wassermann was negative, spinal fluid negative.

Locomotor ataxia is a very unusual disease in children. It is so unusual that the textbooks of pediatrics that I have examined do not even mention it. We have not been able to find any recorded case similar to the one here presented.

1801 Pine Street.

The Recent Recrudescence of Epidemic Infantile Paralysis

HERMAN B. SHEFFIELD, M.D.,
New York

Recently Greater New York has again been visited by a moderately severe epidemic of poliomyelitis. A large number of cases were reported to the Health Department, and, as usual, a far greater number remained unreported for fear of quarantine. Eighteen cases came under my observation as consultant. The disease appeared in a rather mild form. The sensorium was but lightly affected. None of these children suffered from convulsions and the paralysis as a whole was not as extensive and as permanent as in the previous epidemics (1). Moreover, in contrast to the epidemic of 1916 this epidemic was accompanied by few deaths. None of the eighteen children succumbed to the disease. In eight of the patients the paralysis was limited to one extremity, and four of them, in whom the deltoid was mainly affected, recovered almost completely in a few weeks. In six children both the upper and lower extremities were involved, the upper improving very rapidly and the lower more slowly, but thus far (over two months) showing no deformities. Two children had difficulty with the respiratory muscles, in addition to paralysis of the arms. In two cases the gluteal and spinal muscles were paralyzed and were entirely overlooked by the parents. I may add, by the way, that in view of the facts that the recrudescence of the disease in epidemic form was at first not suspected, that the initial symptoms were not characteristic, that the great majority of the patients complained of severe pain in the muscles, and, finally, that as a rule the paralysis set in unusually late (in two cases after ten days), even the physicians in attendance hesitated to arrive at a definite diagnosis, in the majority of instances being inclined to attribute the symptoms to digestive disturbances, rheumatism or influenza. Such errors could mostly have been obviated by bearing in mind the cardinal symptoms of poliomyelitis, whether or not an epidemic prevailed.

In order to obtain a clear conception of the symptom complex of this affection, it is most essential to keep in mind its pathological anatomy. Contrary to what was formerly believed, the lesions of socalled anterior poliomyelitis are not limited to the anterior horns of the spinal cord. It is now definitely established that no portion of the cerebrospinal system is exempt from involvement. Indeed, as is the case with other grave communicable diseases, the lesions are frequently disseminated throughout various other structures and organs of the body. Macroscopically the meninges are found injected and edematous, and the brain and cord moist, translucent and edematous. The gray matter of the cord is also swollen and projects above the level of the white matter. Minute hemorrhages are often discerned in both the gray and white matter, the former frequently assuming a grayish pink hue. The cerebrospinal fluid is but little increased. Microscopically, the pathological process is found to consist chiefly of a cellular exudation, hemorrhage and edema. The lesions are most pronounced where there is an abundance of bloodvessels, i. e., in the cervical and lumbar enlargements, more particularly in the anterior horns. According to Peabody, Draper and Dochez (2), the cellular exudate forms a sheath surrounding the vessels for long stretches, and, in many places, the cells are so numerous as to form thick collars which seem to press on the lumen, thus exerting a mechanical effect in obstructing the circulation. A similar mechanical as well as toxic action is progressing in the inner lining of the bloodvessels, the conjoint pressure soon leading either to hemorrhagic softening or anemia-pressure-necrosis of the infiltrated structures and gradual replacement of the ganglion cells by cicatricial tissue. This terminal pathological stage is often not reached where the pressure is early relieved by absorption of the hemorrhagic and cellular exudates —hence the large number of mild and socalled abortive cases, and the tendency towards spontaneous recovery. As already stated the virus of poliomyelitis is productive also of extensive pathological changes in other parenchymatous organs and in the lymphoid tissues. Pyer's patches and some of the mesenteric glands show lesions resembling those observed in typhoid fever—hence the frequency of abdominal symptoms, e. g., diarrhea, during the course of the disease. The superficial glands of the body, the tonsils, the thymus gland, the liver and occasionally the spleen are considerably enlarged. At a later stage the muscles show definite signs of degeneration. Some of their fibres disappear entirely and others are shrunken, the whole limb becoming atrophied as a result thereof. Often the bones participate in the pathological process.

Corresponding to the complex pathological anatomy of the disease, the symptomatology is equally multifarious. In fact, it may vary in each epidemic. Thus, whereas in 1916 the majority of cases were cerebral in character, in the recent outbreak the spinal types prevailed, as originally described by J. Heine (3). The symptomatology generally manifests itself in the following manner: After an incubation period lasting from three to twelve days and towards the end, indicated by indefinite signs of ill health, such as slight fatigue, irritability, and anorexia, the temperature all at once rises, up to 104° F., the child complains of irregular muscular pain, headache and sore throat, or is seized with an attack of indigestion, more especially vomiting and sometimes diarrhea and more rarely convulsions. Physical examination reveals diffuse congestion of the throat, with or without a slight grayish deposit upon the tonsils, slight rigidity of the neck, chiefly on bending the head towards the sternum,[1] marked paraesthesia, muscular tremor or jerking, distinct drowsiness or stupor (in the cerebral cases) and irritability when disturbed. The mind is usually clear even in grave cases. The heart's action is gen-

[1]This symptom is best elicited by asking the patient, if old enough, to repeat "yes." Whereas normally a child usually emphasizes the spoken word by moving the head downward, in poliomyelitis it hesitates and has to make a distinct effort to do so and yet fails to bring the chin close to the sternum.

erally exaggerated, even with a low temperature. These symptoms may remain stationary for from one to three days or even much longer as it happened in the cases here reported, and then either show a tendency towards spontaneous abatement (abortive type), or get rapidly worse—herald the advent of paralysis. This cardinal symptom is often preceded by progressive muscular weakness, and may remain localized or spread rapidly to other parts of the body, the degree of severity and extent of the paralysis depending upon the gravity and seat of the lesion. In the majority of instances, especially during mild epidemics, the pathological process is limited to the spinal cord (spinal type). In this event the paralysis usually involves the extremities only, or less frequently the neck, abdomen, or chest as well. The paralysis may be partial or total. The extremities are usually affected in the following order of frequency: One leg, both legs, one arm, both arms, one leg and one arm on opposite sides, or more rarely on the same side, both legs and one arm, both legs and both arms, both arms and one leg. Occasionally the paralysis remains limited to a group of muscles or even to a single muscle, e. g., the tibialis anticus, gastrocnemius, or deltoid, and is not rarely overlooked until atrophy has set in. When the muscles of the neck are implicated, the child is unable to hold the head erect; the head falls forward or backward (head drop), or sways from side to side. In paralysis of the abdominal muscles, owing to active intraabdominal pressure by gases, ballooning of the affected muscles is soon noted (Fig. 1) which contrasts strongly with the flatness of the intact muscles. With involvement of the spinal muscles, the patient is either totally unable to turn around or to move from side to side while flat on his back or shows a peculiar clumsiness in doing so. The same holds true when attempting to assume a sitting posture without assistance. This paralysis is often overlooked until frank scoliosis has made its appearance (Fig. 2). Sometimes the paralysis manifests itself in stages, at intervals of variable duration, so that the muscles implicated first may already be on the mend. Where the lesions are limited to the lower neuron the paralysis is flaccid in character, the tendon reflexes are greatly diminished or lost and the reaction to the faradic current is lost. The reaction to the galvanic current may persist for some time longer. Sensation is but slightly impaired. There is no tendency to acute decubitus.

In a small percentage of cases the paralysis, beginning with the lower extremities, gradually spreads upwards (progressive or ascending type, resembling Landry's paralysis), involves the upper extremities, the external muscles of respiration and the diaphragm, if the lesion reaches the upper portions of the cervical cord. Such cases often end fatally from respiratory failure. In another group of patients the paralysis may start in the arms and from here spread downwards (descending type, resembling transverse myelitis) to the lower extremities. In these cases we usually find paralysis of the vesical and anal sphincters, giving rise to urinary retention or dribbling and obstinate constipation or incontinence of feces.

In another group of cases the inflammatory process extends to the medulla (bulbospinal type). The lesion is generally unilateral, and clinically characterized by partial or total paralysis of some of the cranial nerves, in addition to the manifestations observed in the purely spinal variety of poliomyelitis. As a rule the facial and abducens are affected, less frequently the glossopharyngeal and vagus and more rarely still the hypoglossal nerve, in which event the patient presents not only facial paralysis, inwards strabismus, and more or less marked respiratory difficulties (Cheyne-Stokes like breathing, cyanosis and cardiac arrhythmia), but also disturbances of phonation and deglutition. These cases are usually grave, and not infrequently fatal. In the absence of concomitant paralysis of the extremities they are likely to be mistaken for laryngeal diphtheria. I have on several occasions been invited to intubate such patients.

Where the cord remains free and the medulla alone is involved, the tendon reactions are generally exaggerated, the limbs more or less rigid and the gait ataxic in character (ataxic type). It is not at all uncommon, especially in infants in whom the other symptoms are not readily obtainable, for facial paralysis to form the principal symptom of the affection and in the absence of an epidemic to be looked upon as a peripheral facial paralysis (Bell's palsy). The diagnosis, however, can be established by bearing in mind the fact that in nuclear paralysis the palsy is limited to the lower half of the face. Where the pons is also implicated (pontine type, Fig. 3) the symptomatology is further exaggerated by the concurrence of oculomotor paralysis, which may lead to partial or total ophthalmoplegia, and crossed paralysis or hemiplegia alternans.

Quite frequently, especially during severe epidemics, a group of symptoms of poliomyelitis is encountered which greatly resemble those of initial meningitis or encephalitis (cerebral or encephalitic type—polioencephalitis Strümpell), viz., recurrent explosive vomiting, convulsions, rigidity of the neck up to opisthotonos, and marked stupor. Kernig's and Brudzinski's signs are usually inconstant and appear late, and seem to be due rather to the resistance on the part of the child to the painful flexion of the spine. After a day or two partial or complete spastic paralysis of one or of several extremities supervenes, not rarely accompanied by involvement of the facial and other cranial nerves. In some cases there is also marked incoordination of the extremities. The tendon reactions are greatly exaggerated. When the polioencephalitis becomes chronic we have also contracture deformity of the affected extremities athetosis, occasional epileptiform convulsions and feeblemindedness.

As already stated the aforementioned acute symptoms are generally not of very long duration. With absorption of the excessive exudate in the spine and brain and the resulting reduction of pressure upon the vital structures there is a spontaneous tendency on the part of the nerves and muscles to regain their functions. The fever and pain begin to subside and the spread of the paralysis is arrested. The degree and extent of the initial paralysis form no criterion as to the final outcome of the disease as a whole. The author has watched many children seemingly in a hopeless condition to recover almost completely, and, vice versa, mild localized paralyses to persist

for life under the very best methods of treatment. The muscles that fail to recover in about three weeks after the onset of the paralysis begin to atrophy —the limb becomes flabby, cold and cyanotic. The response of nerve and muscle to the faradic current is soon lost, but the galvanic irritability may persist for many months longer. Owing to the laxity of the affected muscles and their inability to hold the articular ends of the bones in apposition, the joints soon become subluxated and with the trophic changes continuing, the limbs lose their shape, often look like mere skin and bone, and even the bones become retarded in their growth. Furthermore, owing to the activity of the intact antagonistic muscles sooner or later diverse deformities make their appearance which remain a source of everlasting misery to the unfortunate victims.

Typical spinal poliomyelitis with sudden flaccid paralysis, especially when occurring during the prevalence of an epidemic, is readily diagnosed even by the inexperienced. When, however, the case appears isolated and pain, for example, forms the chief complaint, poliomyelitis may in the initial stage be mistaken for scurvy, rheumatism or polyneuritis. On careful scrutiny of the presenting symptoms we generally find in scorbutus a history of the slow onset, tumefactions along the long bones, ribs and skull (if need be confirmed by röntgen ray), sponginess and bluish, hemorrhagic discoloration of the gums, and immobility of the extremities as a result of pain and tenderness but not of actual paralysis. In rheumatism also the immobility of the extremities or certain groups of muscles is the direct result of pain and swelling, both of which symptoms showing a great tendency to change their position. Furthermore, rheumatic fever is not rarely complicated by chorea, and endocarditis or pericarditis. The differentiation between a sporadic case of poliomyelitis and polyneuritis often presents great difficulty. In both of these affections pain and paralysis are predominating symptoms in the early stages, and unless there be a history of exposure to poliomyelitis in the one or a history of metallic poisoning or serious infectious disease, especially diphtheria, in the other, I hardly believe that in the early course of the disease one is able to arrive at a definite diagnosis. At a later stage symmetrical paralysis without early recession speaks for polyneuritis, while muscular atrophy for poliomyelitis.

Fig. 1.—Ballooning of the affected muscles.

Fig. 2.—Scoliosis in infantile paralysis.

Fig. 3.—Pontine type of paralysis.

Considerable difficulty is experienced also in distinguishing poliomyelitis from postdiphtheritic paralysis in which the neck and trunk are involved. In such cases attention should be directed particularly to the presence of paralysis of the soft palate, loss of accommodation of the eyes and strabismus which are of rather common occurrence in postdiphtheritic paralysis. On several occasions the author has met with poliomyelitis affecting the laryngeal and respiratory muscles which were erroneously diagnosed and treated (by means of antitoxin and intubations) for laryngeal diphtheria. Such errors can readily be avoided by close scrutiny of the symptomatology and by a throat culture. During an epidemic of infantile paralysis diverse traumatic and tuberculous affections of the extremities lead to diagnostic errors, which can easily be eliminated with the aid of the röntgen ray. Sporadic cases of pontine or encephalitic types of poliomyelitis are frequently mistaken for genuine encephalitis or meningitis. On closer observation it will be noted that in meningitis eye symptoms and Kernig's and Brudzinski's signs appear early and the stupor is much more pronounced. Furthermore, paralysis appears earlier and is more marked in poliomyelitis. In lethargic encephalitis stupor and mask-like face and diplopia appear early and are characteristic, while paralysis of the extremities is usually absent. Some diagnostic aid is also obtained from examination of the cerebrospinal fluid. The latter taken during the early stage of the disease, and especially before the onset of the paralysis, shows an increased cell count with a low or normal globulin content. The lymphocytes predominate. After the first two weeks the cell count usually drops to normal and the globulin content is increased. The sugar content is usually higher than normal, in this respect differing from the fluid of tuberculous meningitis, in which the sugar content is mostly lower than normal. Of course, in tuberculous meningitis the finding of the tubercle bacillus is decisive in the diagnosis. In connection with the aforementioned symptoms the finding of a leucocytosis of from 15,000 to 30,000 with an increase of the polymorphonuclears is corroborative of the diagnosis of poliomyelitis.

With the establishment of the diagnosis our chief concern must be directed to the prevention of the spread of the infection to other children and to the possible arrest of the disease in the patient before irreparable damage

has been inflicted. We have not been very successful in either attempt, since unfortunately, thus far all efforts to isolate the infective agent of infantile paralysis and to produce an efficient antitoxin against it have proved futile, with due deference to the claims of several clinicians to the contrary. To confirm my view let me quote Simon Flexner (4), undoubtedly the highest authority on the subject today. "There is no such thing as artificially produced serum against poliomyelitis, although we have a filtrable virus from the nervous system of patients. We cannot use this material, however, to immunize large animals, such as the horse, in order to get the serum. On the other hand, in a recovered case, in monkey or man, there is for many months in the veins an antiserum which neutralizes the virus of poliomyelitis. Monkey serum cannot be used for man. The animals are too small and too prone to other diseases to utilize their serum. Some measure of success has been attained in using serum of recovered humans in the treatment of other persons." But it can be readily realized that such serum, obtainable as it is under great difficulties (except perhaps during a large epidemic of infantile paralysis), can hardly be utilized and depended upon as a therapeutic or preventive agent. Under the circumstances there is nothing else left but to employ general prophylaxis and symptomatic treatment. The patient should be isolated for about three weeks. All discharges from the mouth, nose and throat should be received on cloths or toilet paper and immediately burned. The feces and urine should be disinfected before their disposal. The sick room should be screened to keep out flies, mosquitoes and other insects. All those known to have come in direct contact with the patient should for a fortnight be carefully watched for suspicious signs of poliomyelitis. During this period of observation children should be kept from school. Cleansing of the nose and throat twice daily with a two per cent. dioxide of hydrogen solution is worth trying in view of the fact it has been shown experimentally to arrest the activity of the virus of poliomyelitis. The same is true of the internal administration of hexamethylenamine, since it has been shown that it finds its way in the cerebrospinal fluid and exerts a germicidal effect. Fifteen grains daily in divided doses usually suffice for this purpose. The milk intended for infants should be preferably boiled.

The active treatment of poliomyelitis during the acute stage consists principally of absolute rest of body and mind and the relief of complicating symptoms as they arise. The patient should be kept in bed in recumbent posture, for about two weeks or longer if acute symptoms persist. Many years of observation have convinced me that the salicylates are actually of curative value in the early stages of the disease. They may be preferably combined with hexamethylenamine, and continued for about a week. Their depressing effect can be overcome by means of digitalis or strychnine, the latter being useful also as a general nerve stimulant. Warm baths, with or without mustard, also act beneficially, both as a nerve sedative as well as a diaphoretic, relieving the system of a certain amount of toxins. Two or three baths in twenty-four hours usually suffice. In undue restlessness the bromides with a very minute dose of codeine will prove very salutary. Lumbar puncture is a sovereign remedy where symptoms of brain pressure, more especially recurrent convulsions, predominate. It may be employed once or twice a day, with the patient in recumbent posture. As soon as the recovery of the affected muscles begins to manifest itself, it is imperative, in order to prevent early muscular contractures and deformities, to immobilize the parts involved. Well padded wire splints for the extremities and a Bradford frame for the spine answer the purpose admirably. The feet should be supported at right angles to the legs. Of course, when the paralysis is definitely established the selection of suitable braces must be left to the good judgment of the orthopedist, always bearing in mind the fact that the less burdensome the apparatus the better for the patient. Early muscular atrophy and deformities may, in a measure, also be prevented by improving the impoverished circulation in the affected structures by means of heat, massage, vibration and electricity. This treatment should begin after the pain and tenderness have entirely ceased. The massage should be gentle, local as well as general, and applied preferably by a professional masseur. Later the massage may be supplemented by light vibratory stimulation. Heat is always indicated in these cases. The patient should be very warmly dressed, and the affected limbs should be exposed daily for ten minutes at a time, to dry heat obtained from a large electric bulb or the numerous violet ray or baking apparatuses on the market. The benefits derived from the use of electric currents has been greatly exaggerated, yet a mild faradic and galvanic current, applied daily for from five to ten minutes, may serve well to hasten muscular recovery by improving its nutrition and promoting conduction of nerve impulses. The consensus of opinion of the profession is at present in favor of getting the patient in a sitting and, if possible, in an upright position soon after the acute stage of the disease has subsided and suitable braces obtained. Where the upper extremities remain unaffected the use of crutches is of great help. At about the same time it is recommended to begin with muscle training, i. e., passive and active motion corresponding to the normal muscular action. This therapeutic measure yields the greatest benefit if executed by one thoroughly familiar with the normal and abnormal powers of each muscle or group of muscles. Otherwise, by exercising the muscles in the wrong direction, considerable harm will be done. It will sometimes be noted that where patients show no muscular power, when put in a warm bath, they are able to make slight use of the extremities, the buoyancy of the water apparently overcoming the heaviness of the limb. It is therefore often of advantage to do the muscle training while the patient is in the bath. Since, however, entire cooperation and attention is most essential to the success of the muscle training, it is quite obvious that these exercises are only applicable in children over three or four years of age. Ample nutrition and general reconstructive tonics, such as strychnine, the syrup iodide of iron and the hypophosphites and codliver oil, are excellent adjuvants in the reestablishment of the dormant bodily functions.

After following the aforementioned suggestions

faithfully for a year or longer without any appreciable benefit to the patient, and, on the contrary, there is a tendency of the deformities to become fixed, there is nothing else left but to proceed with the attempt to correct the deformities by operative measures. The profession is not agreed on the time when an operation becomes indispensable, it is therefore wise to leave the decision of this important question to the good judgment of the individual surgeon. It is well, however, to bear in mind that the surgeon need not be consulted before giving the aforementioned therapeutic measures a very careful and prolonged trial. Furthermore, it is most important to remember that the success of the operative procedures often depends solely upon the skill of the surgeon. Hence the urgency of selecting one thoroughly familiar with this specialty. Of course, even in the best of hands the results are not invariably good. This is true especially of cases which have been greatly neglected or treated by the numerous quacks and fanatics who are forever on the alert to take advantage of the ignorance of the people at a time when their distress and fear is greatest.

Since writing this paper I have had the opportunity, through the courtesy of Dr. I. Lehman, to see the following extraordinary case. The patient, a robust boy about five years old, took suddenly sick with vomiting, diplopia and paralysis of the lower extremities and the left side of the face. Gradually the paralysis extended to the respiratory muscles, and the child died on the sixth day of the disease from respiratory failure. Laboratory examination of the cerebrospinal fluid showed the typical picture of poliomyelitis.

Relationship of Infant and Crude Mortality Rates

DWIGHT M. LEWIS, M.D.,
New Haven, Conn.

A recent article showed that irrespective of conditions, the infant mortality rates for some countries, for districts or cities in those countries, was rather exactly made up of three constants (1). Based on the observations of Brendt and Findlay (2), one constant corresponded to their rock bottom irreducible. A new observation was deduced, namely, that such an irreducible differed according to the sex. That for the male was twenty-five while that for the female was lower by at least five.

A second constant related to filth borne diseases as estimated by mortalities from infant diarrhea and enteritis. The constant for such was 1.23. The third constant related to the respiratory diseases as estimated by mortalities from influenza, measles, whooping cough, pulmonary tuberculosis, lobar and bronchopneumonia, and bronchitis. The constant for such diseases was 2.3. Deriving such constants from the statistics of Brendt and Findlay we found reported and estimated infant mortality rates that were as definitely in agreement in the registration area of the country, the States and of cities as the statistics of such areas were free from unknown and illdefined causes of mortalities. Further it was evident that the possibility presented of both checking up incomplete registration of births and of listing unknown and illdefined mortalities into the scheme to advantage.

A table recently published by the Census Bureau strikingly illustrates these points. This table is given on the next page.

The following opportunities are presented by the table: a, the slight discrepancies between reported and lower estimated rates as in the cases of Ireland and Australia are possible evidence of incompleteness of registration of births; b, the only instance of excessive estimated rates over reported rates in the case of Scotland would point to examination of the reason for the markedly disproportionate rates for whooping cough as compared to the other countries, in comparison with all other specific respiratory rates; c, the evidence that the specific rates for diarrhea enteritis in Australia are higher than in two other countries (sustaining our contention that the low mortality rates are by virtue of continued extremely low respiratory rates; also indicative of lesser yearly variations in rates, one point of argument of this paper); d, the markedly disproportionate estimated and reported rates of Chili. Examination of the unknown rates for the latter country shows for males 34.2, and for females 31.2. Inclusion of these as respiratory corrects the estimated rates for males to 250.2 and for females to 242.5. The balance might well be one of incompleteness of registration of births. A no less important practical point not yet indicated in print would seem to point to the fact that influenza-pneumonia was epidemic for that country as early as 1917. On record that statistics tend to show that congenital debility would ever seem to be a waste basket for respiratory infections (3), the rates for that condition for Ireland and for Chili are suggestive. For Ireland the rates for males was 28.4, for females 24.3 as compared to the rates for Chili of 112.2 and 104.3.

Based on the statistics of Brendt and Findlay, that the same factors making up the excess of mortality over bed rock for the first month of life are part and parcel of the mortality rates that continue throughout life, we were able to show that such was statistically evident (4, 5). In other articles we have shown the apparent relationship between infant mortality rates and crude mortality rates. The opportunity of furthering such a premise in a practical way may do much to place in the hands of the medical officer of health the possible factors concerned in the yearly variations of infant mortality rates. This is the more important for the reason that more widely than ever, social economic factors alone con-

INFANT MORTALITY RATES, 1917, AND SPECIFIC RATES

tinue to hold the stage to the detriment of more exact determination of such variations both by years and of race stock.

We present for consideration of the points at issue the following graphs for three cities, those other than this city being our neighbors whom we constantly use for statistical comparison in the endeavor to elicit facts. The rates in all cases for the period 1910 on (1921-1922 excepted), are those of the Bureau of the Census: those previous to 1910 and 1921-1922 are from city year books or correspondence. The comparative respiratory and filth borne rates are those of the crude mortality rates and have been previously published (5). In order that such curves may be brought into the easiest comparative view with the infant mortality rates, the respiratory field is magnified ten times (per ten thousand of population) and filth borne field is magnified one thousand times (per one million of population). The graphs are as follows:

The usual striking agreement of infant mortality curve with that for the filth borne curve (typhoid-infantile diarrhea content), may be seen to be less so during certain periods of years previous to 1906 and rather continuously so since that year in the case of this city. Examination of the discrepancy at the time that the respiratory field does not interfere is notably seen during 1901. Examination of the statistics shows that the excess of the filth borne curve is one entirely of typhoid and had that disease had the same rate as for the immediate previous years, such a peak as exhibited in 1901 for a filth borne field would more nearly have been an inverted one of at least half a decrease in place of the increase, thus bringing the lower infant mortality rate in harmony with the year's decrease in both respiratory and filth borne disease in so far as infant diarrhea was concerned.

A factor to be determined is the one or more causes which account for an increased infant mortality rate in the event of a well marked decrease of filth borne disease. For example, why should it be that with rates for 1888 and 1893 approximately equal there should have been a decrease of filth borne disease of 27? The same phenomena occurs in contrasting 1917 and 1920. Examination of the increased respiratory curve shows that it is made up of epidemic measles and increased pneumonia. Similarly if we take the increased infant mortality rates for those years where the filth borne is but slightly increased, such as 1895 compared to 1894, 1906 as compared to 1905, 1922 as compared to 1921, the same factor of measles epidemics holds true. Such a factor even holds true in explanation of the slight decrease of infant mortality in 1891, 1893, 1903, where a very decided increase of filth borne disease occurred. Measles epidemics are again a possible factor. It even occurs in 1896 where despite a lower respiratory and filth borne field than the previous year the infant mortality rate is higher. If we take those years of high frequencies of pneumonia with low or absence of measles, 1890, 1907 and 1910 for example, lower or higher filth borne disease curves are approximated by infant mortality rates. Indeed, the year 1918 is the only exception. In the latter instance and to an inconstant degree in other years (difficult to separate from measles influence), it may be that whooping cough enters as an influencing factor.

As previously expressed, the reader would understand that with decreased filth borne disease, the specific disease measles, whether the actual respiratory field was increased or not, was the causative factor in increased infant mortality rates. Such is not the case, I believe, as may be shown by measles mortality under one year of age. The factor is rather, that factor so complicating measles as to cause fatilities, namely, streptococci. Such an event, causing as we have shown, primary disease, even pneumonias, accounts for the exception named in 1918.

Study of the similar graph for Bridgeport shows the same essential features: lowered infant mortality rate in 1901 by virtue of lower filth borne disease (diarrhea) in children under two years of age (an increase for typhoid); incommensurate decrease for 1903 compared to decrease of filth borne by reason of measles; repeated in 1906 and 1914; unaccom-

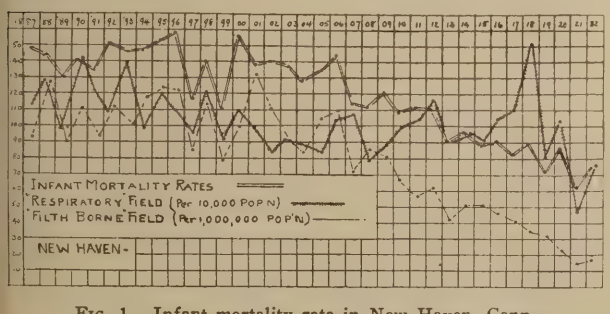

FIG. 1.—Infant mortality rate in New Haven, Conn.

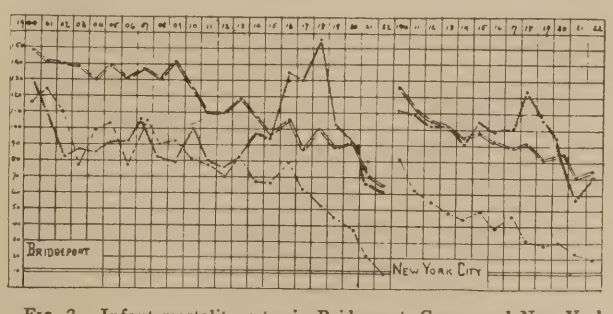

FIG. 2.—Infant mortality rates in Bridgeport, Conn., and New York.

panied increase from pneumonia in 1910 and 1914, 1918 excepted. With practically identical infant mortality rates in 1903 and 1907, in 1904 and 1906, the high measles frequencies would seem the influencing statistical factor.

The graph for New York City would show better could it be resolved into the various constituent boroughs. Notwithstanding, the year 1918, like 1922, was notable for the highest measles rates since 1909. Increased rates for infant mortality with decreased filth borne field are in accord with the graphs for the other two cities. There is one interesting year, 1916, where an abnormally high rate as reasoned by respiratory and filth borne fields exist. A similar one appears for New Haven in the year 1887. The factor of incompleteness of birth registration would be reasonable. If found true, medical interpretation of such graphs would be of yet greater value in checking results.

To the advantage of the medical officer of health is the following. There are occasions where the frequencies of gastrointestinal fatalities are epidemiologically a part and parcel of meningitis, poliomyelitis, encephalitis, and tuberculosis. With lower estimated rates than recorded, we may, to the advantage of conquest of frequencies of such respiratory disease recognize in future such frequencies as a part of some epidemic respiratory disease.

In the main then, we would question whether the conduct of infant welfare in the past ten years more or less of evident excellent control of the filth borne diseases, has gained proportionately. Frankly speaking, have the increased social and economic principles gained the expected results? Are not the results those of cyclic frequency of diseases, respiratory in origin, which diseases are the concealed influencing factors rather than such social and economic factors. Such concealed factors are statistically, year after year, more rationally of influence irrespective of country or district.

From an epidemiological point of view, with consideration of the biology of life as pictured by Pearl, from the history of man, as reflected by vital statistics, a synthetical problem of infant mortality is as follows. Normality or otherwise of the fetus and of the infant is primarily a hereditary normality or otherwise of any or all of the three systems of the human body, namely, the gastrointestinal tract, the respiratory system and the central nervous system. From the influences of maternal infections during fetal life, from the environmental influences of filth borne and respiratory diseases from birth on, may we not find that the selective action of a pathological germ is by reason of defective system. Whether primary or secondary, the variant systemic involvement in the different members of a family at the same or at different periods would fit epidemiological facts. There further may be involved the question whether such defective body tissues are alone hereditary or whether maternal infection during any particular part of pregnancy may as well play a part.

To sum up, yearly variations of infant mortality rates in cities where socalled standard measures for its reduction have been effective for years without decreasing such variations, statistically as well as epidemiologically, would seem to be influenced by the respiratory factor of the crude mortality rate.

Addenda: The following suggestive fact gained since writing this article may well be added at this time. It will be noted that Bridgeport alone of the three compared cities had a lower infant mortality rate for 1922. Both New York City and New Haven had measles epidemics and pneumonia frequencies in 1922, Bridgeport recording their measles epidemic in 1923. For the first six months of 1923, both New York City and New Haven have had a fourteen per cent. reduction in gross deaths under age one, whereas Bridgeport has had an eleven per cent. increase, as compared to the similar six months' period, 1922.

Abdominal Pains in Children Beyond the Age of Infancy*

HARRY S. SNYDERMAN, M.D.,
Philadelphia,
Lecturer on Pediatrics in the Medical Department of Temple University

I know of no symptom which may be more obscure in its etiology than colicky abdominal pain in childhood. In discussing the causes of abdominal pain I am not including any of the referred pains in the abdomen due to acute conditions, such as pneumonia, appendicitis, tuberculosis of the spine, obstructions, and others, but shall try to discuss those pains of which so many apparently well children will complain. The commonest cause, as in infancy, is some form of indigestion, particularly in those cases where the movements contain large amounts of mucus.

The child who suffers from this condition is usually losing weight, his lower eyelids are somewhat puffy or there are dark rings under the eyes, he sleeps badly, is restless and grinds the teeth or talks in his sleep. In the daytime he is unusually nervous, his stools show an excess of mucus, and he complains of pain in the abdomen, which only lasts about a minute, but is severe enough for him to become pale in the face and sometimes to cry out.

*Read before the Samaritan Hospital Medical Society.

These symptoms will repeat themselves many times a day until corrected, if ever diagnosed.

Another common cause of abdominal pain is undigested vegetable matter in the intestine. The stools in these cases are large and show large pieces of undigested fruit or vegetables. It must be remembered that children are likely to swallow their food without mastication, and a vegetable substance, if not thoroughly broken up in the mouth, undergoes but little change in the intestines, causing it to act as an irritant. An examination of the stools of children, complaining of abdominal pain, will at once furnish a clue to the diagnosis and the proper line of treatment.

The teeth should not be overlooked as a possible cause, as where they are defective, and the child is unable to masticate his food, you will have a cause for abdominal pain.

To cite an instance: R. G., aged seven years, was brought to me suffering with severe pain over the lower abdomen for six months. A diagnosis of chronic appendicitis was made and operation advised. The appendix was removed and was found to be inflamed, but the child continued to suffer with the pain until the teeth were treated, when this symptom entirely disappeared.

Next to digestive disorders perhaps the commonest cause of slight pain in the abdomen is the presence of the threadworm, which, although small to produce a mechanical irritation, will cause an excess of mucus to form and that accounts for the pain. Also, such intestinal parasites as the roundworm, tapeworm, and hookworm should not be overlooked, as they are often the causes of abdominal distress.

Another cause is simple constipation, particularly in the child under six years. In the very young child, constipation is an exceedingly common cause of colic, but as the child grows older, this condition improves, as the nervous instability tends to diminish, and consequently bowel action improves. This would bring us to the subject which some writers refer to as the nervous bowel, where the child suffers from a nervous diarrhea, in which the taking of food is almost immediately followed by colicky pain in the abdomen and an urgent desire to defecate, although the stools may not be loose and the child may be free from any such symptom between meals. This condition is closely associated with nervous excitability as almost always the child is nervous, suffers from night terrors and talks in his sleep, enuresis usually being associated. The colicky pain which is started by food is followed as a rule by evacuation of the bowels, though not always.

Sometimes at one meal the child complains only of the abdominal pain, while at another there will also be an urgent desire to defecate. Possibly in the one case the part of the bowel thrown into spasmodic contraction is higher up than in the other case, so that defecation does not result.

Another disorder in which one is tempted to suspect that pains in the abdomen may possibly be of nervous origin is cyclic albuminuria. A morning as well as a midday specimen of urine should be examined in these cases. The vague symptoms for which children suffering with this disorder are brought to the physician are often of a nervous character, such as headache, tired feeling, night terrors, flushing of the face and colicky pains in the abdomen. Children with cyclic albuminuria usually show evidence of digestive difficulties, resulting in excessive formation of gas, as I mentioned above, and in which colicky pain is a common symptom.

Renal calculus, while not a common condition in childhood, should not be overlooked. Two of my patients within the last year were shown to suffer from this, and this diagnosis being confirmed by the röntgen ray, they were finally relieved.

Case I.—M. K., ten years old, was brought to my offices with the following complaints: The child had attacks of vomiting and pain over the abdomen. After having many attacks he was relieved of his pain, until one day it returned and was accompanied by difficulty in passing urine. After twelve hours of severe pain he passed a small calculus. A second patient was not so fortunate, as the stone was lodged in the ureter, and finally passed into the bladder, from which we are still waiting for its passage.

While we are on the subject of kidney, we might also mention movable kidney, as a cause of abdominal pain.

Case II.—A. G., four years old, had severe abdominal pain, and vomiting. Her vomiting was so persistent at times that lavage, the intravenous use of glucose and sodium bicarbonate, the intraperitoneal administration of normal salt solution, sedatives, and other measures, had to be used, but with little result. When a movable kidney was discovered and kept in place, the symptom disappeared.

Biliary colic, which is supposed to be rare in childhood, should not be forgotten. One of my patients who had had many attacks, and many and various diagnoses had been made, was finally proved to have stones in the gallbladder, and the surgeon who operated on this patient still takes pride in the fact that the youngest patient he ever operated on for this condition was only nine years old, and was sent to him by me.

Tabes mesenterica or caseation of the mesenteric glands is a frequent cause of pain in the abdomen, though it is no easy matter to diagnose it, unless the glands are larger and firmer so that they may be palpated.

Frequent recurrence of pain with palpable glands in the abdomen generally indicates some adhesions between the glands and surrounding parts. For the same reason no doubt is the colicky pain which accompanies tuberculosis and peritonitis, and also during recovery from appendicitis, whether the appendix has been removed by operation or not. Last but not least it must be remembered that the earliest evidence of appendicitis may be vague pains in the abdomen, which are not severe enough to cause any alarm to the parents or even to the attending physician. These cases declare their nature by a sudden outburst of acute symptoms of appendicitis, and we all have seen too many of such cases diagnosed too late for operation.

I have grouped together the possible causes of the common complaint of pains in the abdomen. Though it is not always possible to arrive at a certain diagnosis in these cases, one can at any rate, by bearing in mind the various possibilities, exclude some of them in the particular case.

Appendicitis and Peritonitis Complicating Scarlet Fever*

BENJAMIN NEWMAN, M.D.,
Brooklyn

A rare incidence in scarlet fever is its complication by acute appendicitis and peritonitis which may develop during the eruptive stage or during the period of desquamation.

Several instances of this complication are cited in the literature. Kelly (1) speaks of the association of appendicitis with scarlet fever. He asserts that it is not yet determined whether the general infection acts as an exciting factor by preparing a suitable soil for the activities of the intestinal bacteria or whether the specific microorganism is the direct cause of the inflammation of the appendix.

He cites an interesting example: A boy, eight years old, was taken ill with a severe attack of scarlet fever accompanied by abscess of the cervical glands and three weeks later was operated on for acute appendicitis. Turk, while attending the patient, contracted an angina supposed to be due to scarlet fever and fourteen days later he had an attack of appendicitis. Blood from Turk was injected into a rabbit and on its death, streptococci were obtained from the heart's blood. Billings (2) notes the clinical coincidence of appendicitis with general infectious diseases, with attendant bacteriemia. Rosenow (3) by well directed clinical and laboratory investigation has shown conclusively that appendicitis may be the result of a bacteriemia.

Out of a series of five thousand cases of scarlet fever reviewed by McCollum and Place (4) peritonitis actually occurred in four. In these the attack of scarlet fever was not especially severe. Huebner (5) states that some general purulent cases of peritonitis, occasionally preceded by appendicitis, are met with in scarlet fever. According to Canelli (6), appendicitis is a rare complication of scarlet fever, only fifteen cases having been reported in the literature. He cites a fatal case in a child two years of age. Dunham (7) publishes a review of ten cases collected from the literature between 1903 and 1919 and reports a case in a girl five years of age in whom appendicitis developed two weeks after the beginning of an attack of scarlet fever. Sutton (8) mentioned a case of a young man of nineteen years who recovered without operation. McCollum and Blake (9) state that it is possible that mild peritoneal involvement may be found on careful examination to be more common than is at present believed. Tice (10), however, states that appendicitis and peritonitis complicating scarlet fever is an accidental association and believes that such observations are merely coincidences.

CASE REPORT

Case.—L. R., six years of age, was admitted to the Kingston Avenue Hospital on April 14, 1922. Examination revealed a fairly well nourished male child with a moderately severe scarlet fever infection. He showed a typical punctate erythematous eruption, congested throat and prominent papillæ of the tongue. Pastias and Rumple-Leede sign was positive. There was no nasal discharge. The ear findings were negative. The heart was rapid and regular with a slight systolic blow at the apex which was not transmitted. The lungs were normal. On admission, the temperature was 102.3°, pulse 120, respiration 24.

The disease was running a usual course until the fifth day after admission when the patient's temperature rose from 101° and fluctuated between 102.4° and 103.4°. Two days later the patient vomited and complained of abdominal pain which was generalized. He was more tender on palpation over McBurney's point. Muscular rigidity was marked on the right side. There had been no movement of the bowels during the two days prior to the attack of abdominal pain.

There were 12,000 white blood cells; polymorphonuclears, 84 per cent.; large lymphocytes, 12 per cent.; small lymphocytes, 4 per cent. Several specimens of the urine showed a faint trace of albumin and a few pus cells were observed at times.

The patient was operated on the second day after the onset of abdominal pain by Harold K. Bell. A localized mass was found in the appendicular region from which about two ounces of pus escaped. The appendix was found dipping over the brim of the pelvis, the distal two thirds greatly distended and actually inflamed with a perforation near the tip. The appendix was removed and drainage instituted.

The boy's convalescence was delayed by an attack of measles. On June 1, 1922, his wound was entirely healed and he was discharged twelve days later in good condition.

Seasonal Curves in Mental Disorders*

FRANK PARSONS NORBURY, M.D., F.A.C.P.,

Jacksonville, Illinois

The observation of seasonal curves as climatic factors in the occurrence of mental disorders was first studied in Continental Europe, over fifty years ago. Only since 1886, however, have data been compiled which show maximum and minimum curves covering various forms of mental disorders. Suicide is included in these curves, for the reason that in the majority of cases, it is evidence of the presence of mental disorder. Sufficient data are now available to warrant the belief that mental disorders occur in seasonal curves and that climate has potential values in their incipiency and recurrence.

One of the graphs, which I have prepared, presents statistical data of first admissions and readmissions in some of the State Hospitals for the Insane in our country. This graph is representative of our country as a whole, as it is really a cross section including institutions extending from the extreme East to the extreme West, the data being compiled by the statistician of the National Committee for Mental Hygiene. It will be noted that the maximum curve is attained during the months of March, April, May and June, and that there is a gradual decline from June until October, when the minimum curve begins and reaches its height in November. Then follows a gradual decline until February, when again a regular and unbroken curve is shown, which reaches its maximum in the spring months. We always have a rise in the spring and autumn.

The spring rise differs in height and duration. It may reach its maximum height in March but is continued through April, May and June. If the maximum height is delayed until May or June, the duration of this height will remain approximately the same; the gradual decline not commencing until July. The minimum or autumnal curve may reach its height in September. If so it will be of longer duration than if it is delayed until October or November. If we could have a graph showing all first admissions and readmissions for a period of twenty-five years, then I am sure all local or accidental factors would be removed. We would then have a true cross section, showing the maximum and minimum seasonal curves for our country.

I will show my own observations extending over a period of twenty-two years. While the numbers are not over three thousand, yet the seasonal curves are in evidence. Massachusetts, New York and more recently Illinois are now giving scientific statistical study to the problems of insanity, and graphs from New York, Massachusetts and Illinois are presented herewith. The one from Illinois is taken from the first published report of the recently organized department of statistics. Then other slides will show the annual incidence of insanity in London, the curve of annual incidence of paresis in Paris, and the suicide curve in London. These graphs are from studies in the *Psychology of Sex* by Havelock Ellis.

The interpretation of seasonal changes in the human organism belongs both to the meteorologist and the physiologist. Much constructive and definite observational work along this line has been done by one of your members, Huntington. It was while reading his contributions as they appeared in *Harper's Magazine* that I became interested in his seasonal efficiency curves. The fact that they parallel the seasonal curves of mental disorders created an opportunity for clinical analysis of the problems presented. I have prepared a graph of Huntington's findings showing the efficiency of factory operatives in which the maximum and minimum curves have relative correspondence to the mental graphs. The graph also shows seasonal changes in mental and physical activity have corresponding spring and fall variations.

The similarity of these various curves from the viewpoint of a clinician, means that there are common environmental factors concerned both in promoting the highest degree of efficiency and in the production of physical exhaustion, the chief underlying factor in the causation of mental disorder. That common factor is climate. The human periodicity of efficiency corresponds with the human seasonal periodicity of mental disorders.

Mental disorders are regarded as affections of the brain with predominating, but not exclusive, psychic

*Read before The American Meteorological Society, at Cincinnati, Ohio, December 29, 1923, and the Chicago Neurological Society, March 20, 1924.

symptoms. They are more inclusive than the groups included under the term of insanity. Insanity is a legal term and, as such, it has to do with the competence of the person to manage himself and his affairs.

Psychiatry must consider all factors which enter into the clinical problems. As a result, Lugaro says, it is seen that "psychiatry touches upon and embraces all of the most intricate problems of biology and medicine and contains many others which belong to it exclusively." The human body is an automatic self regulating machine of "unfathomable complexity and extreme plasticity" acted upon from within and from without by varied and innumerable stimuli. Further, man, like all living animal and vegetable life, possesses adaptation of each part of the living being to the whole, and the whole organism to the environment in which life exists.

The phenomenon of adaptation is fundamental to the biological conception of life. In man the question of adaptation is increasingly heterogeneous. Climate and food are obviously the most important of the environmental factors concerned in man's adaptation, his maintenance as an individual and for the preservation of his species. The laws of selection, adaptation, conflict and others, concerned in social evolution, when applied to our biological problems reveal to us the importance of climate, food and physical fitness in survival of the stronger and with the quasi elimination of the weaker or less fit.

Mental stability is man's greatest asset in meeting the problems of everyday life. The correlation of mind and body need not concern us here. Mental disorders have their inception and are kept going "because certain pathways along which morbid ideas, doubts and fears tend to pass are fixed and the inertia of the nervous system to old connections and associations are not interrupted but allowed to persist and no new pathways are made."

The dysfunctioning to which morbidity of mind is due is found, primarily, in the phenomena of exhaustion. The exhaustion may be in the lack of potentials in the stock. It may be acquired, therefore individual and due to any one, or their combination, of the great number of causes of exhaustion. It is not easy for man to realize how much he owes to the restraints and supports of the social fabric in which he is an element and which, like the atmosphere, always and insensibly surrounds him. These factors contribute likewise to his undoing, when exhaustion enters to contribute to inability to meet the demands placed upon him.

Exhaustion is a fact and not a fancy in being the primary factor in the etiology of mental disorders. A simple definition of exhaustion may be expressed

as follows: A diminution of muscular and intellectual power and accompanied by inability of the individual to respond to stimuli. Abnormal fatigue is first in evidence. This may lead to mental disorders, which Dercum calls the "fatigue neuroses," which, as entities of disease, have definite clinical value. To understand the clinical pathology of exhaustion and its contributions to clinical psychiatry we approach our problems along the line of physiological, chemical and psychological inquiry.

Crile emphasizes the fact that man has not been presented with any new organs to meet the requirements of present day civilization; indeed, not only does he possess organs of the same type as the savage, but also, the same type as those possessed by the lower animals. It is largely through the emotions that mental perturbations receive their stimuli. Cannon has shown that these mechanisms are through the autonomic nervous system. Under the continued stimulation of the primary emotions, fatigue, exhaustion and death occur, due to the fact that exhaustion is central in origin; that is, primarily within the brain.

The clinical pathology of exhaustion is always the same, however produced. Exhaustion begins and ends in the cells. The cells involved are those concerned in converting potential energy into kinetic energy, viz: the brain cells (the central power house), the thyroid, adrenals and liver cells. All of which have integrative and supporting action in directing and controlling the mechanistic activities of the body. In order to grasp fully the mechanism of exhaustion the phenomena of sleep must be considered.

Sleep is nature's restorer in the rehabilitation of cell functioning. While the phenomenon of sleep has not been solved, yet the research work of Crile has shown it is due to some physicochemical process and clinically speaking, he says, that exhaustion is not overcome without the intervention of sleep. Crile insists that sleep and sleep alone can accomplish restoration of the original condition of cell life.

There is a constant relationship between exhaustion and certain physical changes in the cells of the brain, thyroid, adrenals and liver, as proved by Crile. The fact that restoration takes place by timely intervention of rest and sleep emphasizes the importance of the rhythmic factor in the physical activities of the body. The rhythmic factor is concerned in the electrical conductivity and processes of the cells. Crile says that in every case of exhaustion there are changes in conductivity with corresponding histological changes in the cells.

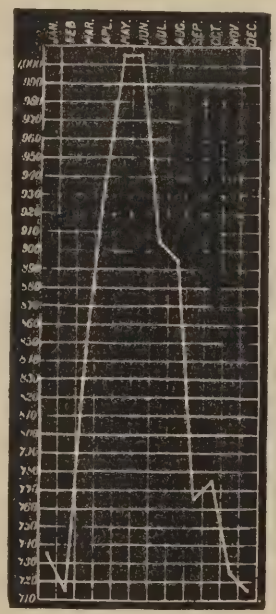

FIG. 8. — The suicide rate in London.

The human body, in its electrochemical mechanisms is responsive in health and in disease to the laws of physics. During sleep the battery (the brain) is cleaned, and recharged with potential nervous energy. The reverberation of these powerful charges throughout the nervous system when supported by the body viscera contribute to the joy of living. The degree of well being depends on nervous tension and harmonious adjustment of all integrative rhythmic physiological functioning. This harmonious adjustment is the foundation of mental equipoise and contributes to fair dealings with self and the outside world. Harmonious adjustment is individual, being interwoven with personality, character and the inherent reserve or the individual's capitalization of potential nervous energy. There is a diurnal rhythmic variation of this reserve which we all experience. Our best hours for work are in the morning after a restful night when sleep has cleaned and charged our cells. As the fatigue products enter to inhibit the output of nervous energy and lessen its tension bodily work diminishes. We are less in-

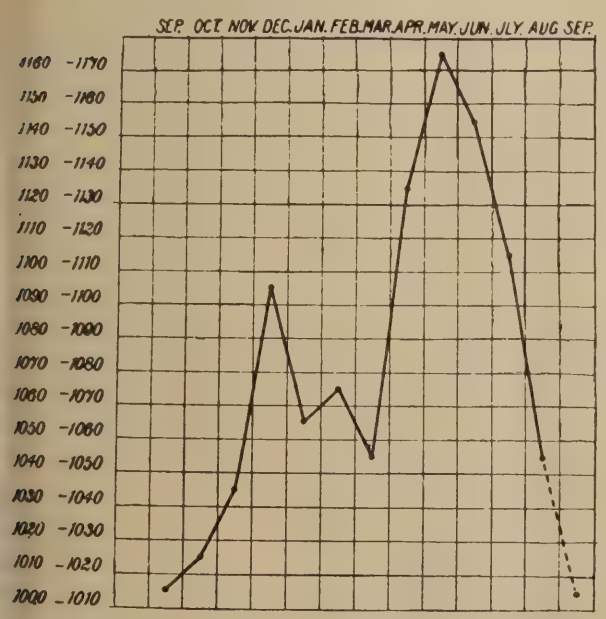

FIG. 7.—The annual curve of the conception rate in Europe.

clined to exertion and more to repose, less confident and more conservative as night approaches. Ordinary or normal fatigue is responsible for the inhibitions and lessened response to stimuli. Abnormal fatigue means inadequate readjustment and accumulated inhibitions with the way opened for the more profound clinical manifestations of exhaustion.

There are longer intervals than the diurnal tides which affect bodily activities. Days and perhaps weeks or months may go by when our output of nervous energy meets all demands; when strenuous efforts are really enjoyed and the difficulties which confront us are surmountable. On the other hand, there are rhythmic periods of "blue Mondays" when weariness, depression, low nervous tension prevail and contribute to lessened output of work and a disheartened mental attitude. In both conditions bodily fitness to respond to stimuli, to the waves of energy from within and from without, is accompanied by reactions in conduct, which are registered as mental accompaniments with varying feeling tones. This rhythmic physiological impress both normal and abnormal includes all functions of the body, even to the smallest capillaries of the vascular system.

It is through the integrative action of the nervous system that rhythmic impress is made. Havelock Ellis says, the general tendency, physical and psychic, of nervous action to fall into rhythm shows a biological predisposition to accept any periodicity that is habitually imposed upon the organism. Man is responsive to the daily cycle, to weekly, monthly and seasonal cycles, as to his output of work, his mental equipoise and his well being.

Climate with its seasonal variations thus enters into the problems of clinical medicine. Climate variations, as shown by Huntington, are factors in industry, education and civilization itself. He has not applied study of climate to the conduct curve of man as a social unit in the problems of social evolution.

It is this conduct curve which encircles us in the problems of mental disorders. Climate, with its seasonal changes, is responsible for the shifting of metabolic processes, and the seasonal periodicity which enter into the growth and development of children and the shifting from the ordinary grooves of conduct of childhood to the reproductive channels (psychosexual) of the adolescent. There are many facts to show that psychosexual activity is greatest in early spring and late autumn. Further, the conception curve, according to Ellis, is highest in April, May and June of the spring months and again strongly worked in November. Ellis concludes that the sexual rhythm is a physiological reaction to the cosmic influences of the earth's seasonal rhythm.

Another interesting seasonal observation, which Ellis says is not accidental coincidence, is in the mortality of children under one year of age. Children born in February and September and, therefore, conceived in May and December appear to possess the greatest vitality, and those born in June and, therefore, conceived in September have the least vitality. May and December are precisely the periods when conceptions are at their maximum and September is precisely the period when they are at a minimum; so that, if the coincidence is not accidental, the strongest children are conceived when there is the strongest tendency to procreate, and the feeblest children when the tendency is the feeblest.

This factor may, in my judgment, represent the endowment which the child brings with him into the world, which is to function with environment and circumstance in his conflicts in everyday life.

It is to be said that mental disorders are not the only clinical entities produced by exhaustion affecting the neural mechanisms in which seasonal curves are to be noticed. Some of the varied infectious diseases have exceptional potential toxins which are intense nervous poisons and produce direct and indirect pathological conditions, recognized as disease entities. Inasmuch as infectious diseases owe their existence to pathogenic bacteria and the incidence of such diseases are dependent upon seasonal variations, modern research workers are now endeavoring to correlate the presence of such diseases with varied seasonal virulence of pathogenic bacteria.

Before the Mayo Clinic, Rochester, Minn., Nakamura recently reported a study extending over a period of one year of bacteria isolated from diseased tonsils, the tonsils being removed because they were believed to be the foci of infection in patients suffering from various diseases. The study revealed marked variation in the types of streptococci from week to week, but more marked according to the season. The curves brought out conclusively a seasonal variation in the virulence of these disease producing agencies. Rosenow, in discussing the paper, said the increased prevalence of tonsillitis during the winter months may be due more to climatic conditions than to contact infection. Again, many of the mental and nervous disorders are of post infectious origin and called the sequelæ of such diseases. The lessened resistance, with the personal equation of nervous predisposition, contributes favorable soil for the development of the mechanism of exhaustion, and explains, too, one of the reasons why mental and nervous conditions, as sequelæ, follow the seasons when infectious diseases are most prevalent. Climate again enters as a responsible causative factor in mental and nervous disorders.

Huntington says "man is more closely dependent upon nature than he has realized. A realization of his limitations is the first step toward freedom." And again, "If we can conquer climate, the whole world will become stronger and better."

CONCLUSIONS

1. Climate is a formidable and integral part of human energy.
2. The output of human energy (the efficiency curve) has climatic seasonal variations (Maximum curve in the spring, minimum curve in the autumn).
3. Exhaustion of human energy with its very varied phenomena as represented in disease entities has climatic seasonal curves.
4. Exhaustion of human energy is the chief and most formidable causative factor in all forms of mental disorders.
5. Mental disorders in their incipiency and recurrence parallel the efficiency curves of Huntington (Maximum in the spring, minimum in the autumn).

6. The common factor of climate contributes to the standards of human efficiency and sanity, and to the conditions of exhaustion responsible for mental disorders.

Intracranial Pressure; Its Determination and Significance in Neurosurgical Conditions*

A. S. MACLAIRE, M.D.,
New York

By increased intracranial pressure is meant the increase of pressure within the cranial cavity, and it is due to interference with the cerebrospinal fluid circulation, whether intracerebral or extracerebral in origin.

Normally a direct ratio exists between the arterial blood pressure and the intracranial pressure. When a pathological situation arises, the former normal proportion becomes altered. Logically one would deduce that as the blood pressure increases, so should a parallel rise in the intracranial pressure occur; and as the blood pressure falls, so should the intradural pressure decline; but this supposition is fallacious when considering abnormal cerebral conditions. The parallel rise in arterial blood pressure corresponding to the intracranial increase does occur, it is true, but only as a late and delayed sign when permanent cerebral tissue damage has already been produced. Brain tissue, as all are aware, never regenerates once destroyed. The ideal desire in all neurosurgical conditions is for an early diagnosis and as blood pressure is a late indicator, some other means must be sought.

The various branches of the vascular tree differ in their blood pressures, being highest in the arterial system, next in the capillary network, and lowest in the venous circulation. When an intracranial condition arises and the cerebrospinal fluid system is altered in some respect, whether in the form of a hypersecretion of the cerebrospinal fluid due to an irritant, or an interference with the absorptive area or an encroachment upon its circulatory channels, then a certain amount of stasis must naturally occur within the cerebrospinal fluid system. With an increase in the total amount of cerebrospinal fluid within the calvarium, a rise in the intracranial pressure results, and with such a situation pressure occurs upon all the intracranial contents; the less solid or compact the structure, the greater the compression upon that particular structure. As the vascular system consists of a set of hollow tubes with a fluid substance flowing through them, and also with a varying degree of pressure, depending upon what branch of the tree it is, so will the compression effect vary. With this in mind, it is natural enough to conclude that the veins, possessing the lowest pressure, will be first the structure to be affected. The result of this compression is to produce a venous congestion of varying degree, depending upon the intracranial pressure. With an increase in this venous congestion, a secondary decrease in the cerebrospinal fluid absorption is produced. Since eighty per cent. of the cerebrospinal fluid is excreted through the supracortical veins and the other twenty per cent. by the Pacchionian bodies along the superior longitudinal sinus, it is easy to see how a vicious circle is thus produced. With the continued secretion of the cerebrospinal fluid by the choroid plexus of the lateral and third ventricles and a small amount in the fourth ventricle and a decreased absorption or excretion of this fluid, together with a continued increase in the venous congestion due to the increasing intradural pressure, it is not difficult to conceive to what degree the intracranial pressure may rise when the capillaries and finally the arterial system are also involved in this external compression.

The determination of increased intracranial pressure resolves itself into the clinical observations, namely, symptoms and signs, and the instrumental or mechanical findings. Again, the symptoms and signs may be subdivided into the two main groups of general and focal. Among the frequent general symptoms and signs are headache, projectile vomiting, dizziness, vertigo, visual impairment of varying degree but always growing progressively worse, various degrees of somnolence and coma or insomnia, slowed pulse and respiration, gradually terminating in the Cheyne-Stokes type of breathing, various forms of mental aberrations and changes in disposition. The focal symptoms and signs depend upon the site of the brain involved and a knowledge of the anatomy and physiology of the brain is essential.

The mechanical methods employed in diagnosing increased intracranial pressure are, in the order of importance and significance, 1, the spinal mercurial manometer, 2, the ophthalmoscope, 3, the blood pressure apparatus and 4, the x ray.

The spinal mercurial manometer is an apparatus of more or less recent addition and still more recent adoption by the profession. There are several mercurial manometers on the market today, in addition to the water manometer. The general principle of all the mercurial apparatuses are the same and the

*From the Neurosurgical Department, New York Polyclinic Hospital and Medical School. Delivered at the Neurosurgical Conference at the New York Polyclinic Hospital, March 5, 1924.

description of any one will answer for all and will suffice for our purpose. The best known mercurial manometers are those of Jackson, Fleischer and Landon. The only advantage that the latter two possess over the former is merely a matter of size; the latter two can easily be carried in a coat pocket, whereas the Jackson outfit is a little large for that convenience. On the other hand, the Landon manometer has the disadvantage in that the stop cocks very often become clogged owing to the spinal fluid coming into contact with them. In the Jackson apparatus, the simplest of all, spinal fluid at times enters the glass manometer tubing, but that is easily cleansed with saline, alcohol and ether rinsing. The same slight accident at times occurs in the Fleischer apparatus but it is of less importance here.

The principle of all the manometers is that of a U shaped glass tube containing mercury, a scale graduated in mm., a rubber tube which is attached to one end of the U tube and the other fitted into the lumbar puncture needle by means of a connector or adaptor. The entire procedure consists in performing a lumbar, cistern or ventricular puncture, inserting the adaptor into the exploring needle or cannula and noting the height to which the column of mercury rises in the tube. The scale, parallel to the tube, signifies the pressure in mm. Hg. In a child the normal intracranial pressure on such a mercurial apparatus is 5 to 7 mm. Hg., and in an adult it is 7 to 9 mm. Hg. The mercurial manometer is the most delicate and most accurate of all the mechanical devices. In addition, it registers the faintest rise in intracranial pressure and is the earliest indicator of intracranial disturbance. The manometer does not fail, as does at times the ophthalmoscopic picture of the optic disc. It can safely be claimed for the spinal mercurial manometer that it is the earliest and most reliable detector of increased intracranial pressure.

The next important and reliable instrument is the ophthalmoscope. The ophthalmoscopic findings are a matter of personal interpretation in the early stages of optic disc changes and sufficient opportunity is present for differences in opinion, whether there is slight engorgement of the veins, whether the nasal margins of the discs are blurred, whether the picture observed is at all significant of an early beginning pathological condition. There is at least here grounds for dispute and variations of opinion. The mercury registers automatically and discussion as to the interpretation of the scale reading is eliminated. The manometric findings are not a matter of personal equation but are the same for all who execute the technic properly.

In many intracranial conditions where one would naturally expect fundus changes, it is surprising how often we find our expectations not materialized—the discs happen to be normal when we anticipated choked discs or at least some papilledema. Thus, though the ophthalmoscope is a most valuable instrument and its findings are of great significance, yet both are only second, at best, to the infallible, perfect mercurial manometer.

The increased blood pressure determination is a very late sign of increased intracranial pressure. Only when the compression has already involved the medulla does the blood pressure rise to assert its importance. But who wishes to delay and to defer a diagnosis until the late signs become evident? This is an age of attempted early diagnosis and we are all striving for that goal. With this, we can dismiss the blood pressure apparatus from vital consideration in most neurosurgical conditions.

The x ray is merely mentioned for completeness. As an aid in the diagnosis of increased intracranial pressure, it is not only a late sign but a prolonged and advanced sign. To obtain sufficient thinning, rarefaction or absorption of the calvarium as a result of increased intracranial pressure, the case must be one of extremely long standing. The value of the x ray in the diagnosis of this condition is practically nil, and in the early cases it is absolutely nil.

The common neurosurgical conditions which are most likely to have associated with them increased intracranial pressure are, 1, intracranial neoplasms; 2, intracranial abscess; 3, large sized hemorrhages, traumatic or otherwise, supracortical or extradural in position; 4, internal hydrocephalus; 5, external hydrocephalus; 6, acute brain injuries with the development of traumatic cerebral edema of some degree and 7, localized serous meningitis.

The time of appearance of increased intracranial pressure in brain tumors is apt to be manifested earlier in those neoplasms where the pathology is that of new tissue formation and where the tumor is a true addition to the total brain substance itself, as in sarcoma or endothelioma (meningioma as Cushing terms them at present). In considering meningioma one must remember that they are not true brain tumors in that their origin is from the meninges and not from the cerebral tissues. On the other hand, the intracranial pressure increase may be delayed and insidious in onset in brain tumors such as gliomata, where the pathology is a gradual infiltration of the cerebral tissues itself, in fact, such tumors may be considered cases of hyperplasia of the connective tissue structure; yet increased intracranial pressure is present even in cases of gliomata by the time the neurosurgeon is called into consultation.

The term intracranial abscess is preferred to the more common usage of brain abscess, for the reason that the latter term must imply brain tissue destruction and replacement of the same by purulent material. Extradural or leptomeningeal abscess is not in the literal sense of the word a brain abscess, though it is an intracranial abscess, and this discrimination in terminology should be strictly adhered to. In the early stages of true cerebral and cerebellar abscess, increased intracranial pressure may be either entirely lacking or show only a slight rise. The explanation for this lies in the classification mentioned above, namely, that it is a replacement of normal tissue by a pathological substance and not an addition to the total cranial content. In leptomeningeal or extradural abscess, the situation is different in that a foreign mass has been added to the normal cranial contents. Increased intracranial pressure will be evidenced early in this condition.

Intracranial hemorrhages into the brain tissues do not as a rule produce an increased intradural pressure. When the hemorrhage is of sufficiently large size and is either supracortical or extradura, the hemorrhagic clot acts as a new growth in that the

normal skull contents are increased and, in addition, interferes with the normal excretory channels of the cerebrospinal fluid. Besides, the blood clot occupies and, thereby, obliterates a certain portion of the absorptive area of the cerebrospinal fluid. The localized stasis of cerebrospinal fluid thus produced is the beginning of an external hydrocephalus and as the latter condition progresses, increased intracranial pressure becomes more evident.

Internal hydrocephalus is produced by an obstruction to the ventricular system in some part of its course either by a neoplasm or by firm adhesions, the result of prenatal or postnatal meningitis. The socalled cases of congenital internal hydrocephalus have been demonstrated on careful microscopy to have been the end process of an intrauterine meningeal condition. There are several types and degrees of internal hydrocephalus depending upon the site of the pathology and the duration of the condition. If the foramen of Monro on either side should be occluded, then a unilateral internal hydrocephalus would result. This particular type of case is extremely rare, though occasionally in a large series one is likely to meet with it. The more common forms are those where the blockage occurs either at the aqueduct of Sylvius or at the foramina of Luschka and Magendie. In the former event both lateral and third ventricles become dilated and in the latter case all the brain cavities including the fourth ventricle become enlarged. To produce a hydrocephalus of the fourth ventricle all three cerebellar foramina must be occluded.

Some authors subdivide the old classification of external hydrocephalus into the nonabsorptive and hypersecretive forms. In the former instance a normal amount of cerebrospinal fluid is secreted by the choroid plexus but the absorptive power of the subarachnoid spaces is lowered and, therefore, a stasis occurs on the external surfaces of the cortex and in the various cisterns. In the latter condition the manufacture of cerebrospinal fluid by the choroid plexus is so markedly increased that the normal excretory channels are unable to cope with the cerebrospinal fluid production and, thereby, a certain amount is always left unabsorbed. With the secretion constantly in excess over the excretion a condition of external hydrocephalus soon presents itself. There is a form of hydrocephalus which is a combination of both forms, namely, the nonabsorptive and hypersecretive. This type, as would be anticipated, is the more serious of the forms of external hydrocephalus.

Another form of hydrocephalus is that in which there is a coexistence of internal and external forms. In these cases the most plausible explanation is that originally the condition was an internal hydrocephalus with the expected dilatation of the ventricles and later the obstruction being destroyed or torn, with the result that the sudden release of a superabundance of cerebrospinal fluid into the subarachnoid spaces over and above its excretory power, converted some of the internal into an external hydrocephalus.

In the internal type of hydrocephalus the blockage of cerebrospinal fluid produces an increased intracranial pressure provided the cranial suture lines and fontanelles are closed; if, however, they are still open, the intraventricular pressure, instead of being registered as increased, remains normal at the expense of the separation of the sutures and enlargement of the fontanelles. With the firm union of the suture lines and closure of the fontanelles the intraventricular pressure increases at the expense of the cerebral tissues. In external hydrocephalus, where a stasis, occurring on the surface of the cortex, interferes with the normal excretion of the cerebrospinal fluid, the increased intracranial pressure varies directly with the degree of obstruction of the absorptive powers of the cerebrospinal fluid.

In cases of acute brain injury increased intracranial pressure develops only when traumatic edema is associated with the initial trauma. The etiology of this cerebral edema may be explained upon several hypotheses. It may be the result of a transudation of blood serum as is found in contusions elsewhere in the body. Again, it may be due to a traumatic irritation of the choroid plexus, caused by a sudden mechanical stimulus with the production of a hypersecretion of cerebrospinal fluid and a resultant cerebral edema; or as a result of the cerebral congestion there is a retardation of the normal excretion of the cerebrospinal fluid with the ultimate production of an external hydrocephalus or wet brain; or it may be due to a combination of the latter two suppositions.

By a localized serous meningitis is meant a localized collection of cerebrospinal fluid within the leptomeninges, well walled off by adhesions and not infected, producing signs of increased intracranial pressure in the same capacity that a dural meningioma or an extracerebral abscess does. The term, localized serous meningitis, employed today is a misnomer and should be replaced by a more descriptive term as noninfective localized meningitis. These conditions are usually found following ear complications and especially after mastoid operations.

To be capable of detecting early the presence of increased intracranial pressure or to be able to have definite knowledge that the intradural pressure is increasing, is from the viewpoint of differential diagnosis alone of sufficient importance to warrant the universal adoption of this delicate test. The routine employment of intracranial pressure determinations by means of the spinal mercurial manometer will serve to differentiate many neurological from neurosurgical conditions. In addition, many neurosurgical diseases will be discovered at an earlier period in their development when surgical treatment will offer the possibilities of a better prognosis than most neurosurgical conditions do at present. The persistence of a chronically increased intracranial pressure produces in the end not only mental impairment and emotional instability, but also is very likely to produce total and permanent blindness, provided the pressure is sufficiently high.

We owe it to our patients to detect increased intracranial pressure early, to institute proper therapy immediately and to explore surgically when the lesions are small before permanent cerebral damage has occurred. The accurate measurement of increased intracranial pressure should be the first commandment of the neurosurgeon's bible.

The Child Family Relation: a Psychosexual Study

J. F. W. MEAGHER, M.D., F.A.C.P.,
Brooklyn

The child parent relationship as a psychological problem is one of the most important we have to deal with, and yet is probably one of the least generally understood. Certainly this is true in regard to the psychosexual phase of this problem. Every physician should have some knowledge of the genesis of the psychosexual life. Hitherto the literature paid much attention to the physical side and gave but little consideration to the mental aspects.

However, only in the past twenty years has the discussion of sex been dignified by its presentation before learned societies. Jung has said that the objections to the discussion of sex, in most people, are not intellectual, but are founded on a feeling of moral resentment. So one is advised to go guardedly into the sex history of certain types of patients. The attitude of the examiner is more important than the sort of questions he asks.

The youth's attitude toward the question of sex is very important—more important probably than any childish expression of the impulse. We are well aware that habitual abnormal phantasying in a child may result in later abnormal traits and trends. To get at the real factors in the individual patient, one must approach the subject sympathetically, and not with dislike nor disdain.

While it is granted that there are other impulses in life besides the sexual, nevertheless sex issues lie at the heart of our emotional life, particularly the hidden sex influences. The emotional content in sex is admitted by all students of human character. And emotional experiences produce the greatest reactions in man.

Because none of us has any conscious memory of our first five years of life, is the reason why we regard these years as unimportant in shaping our character. As a matter of fact psychopathologists agree that they are the most important years of our lives, as far as character moulding goes. In fact, early life experiences are the basis of character. They remain dynamic throughout life—even though there is amnesia for the experiences themselves.

One can in truth say that character is determined absolutely by the guardians of the first five years of life. An individual's fundamental (not compensatory) traits are formed by the time he or she reaches the age of five years. Any observer can prove this by observations on his own children.

Heredity, alone, will not explain character traits. The environmental influences probably have great weight. In this way we can explain how it is that parents' traits are passed on to the children. Emotional difficulties in a parent or grandparent will show in the children or grandchildren. This theory is applicable to sex reactions. The child is conditioned (unconsciously) to react to sex in accordance with the parent's attitude; this colors its own later (adult) attitude. This is important to remember.

One can say that if a child has normal traits at the age of five, it is not likely to show hysteria in later life. One can also say that a spoiled child is apt to be a spoiled adult.

Character has to do with our traits and trends. It manifests itself by the way we use the material that is in us. All individuals have two tendencies; one, the infantile regressive way, to draw within himself (common in the neuroses); the other, the adult way, to project himself into the environment. Character has more of an emotional than an intellectual origin. It is formed in general by the interplay of the individual and his social environment.

One's character might be described as a condensation of one's history from birth, with prenatal influences added. As Henri Bergson, the distinguished French philosopher, says, we feel and act because of our past, though we are aware of only a small part of it in the form of ideas.

The most important element in the diagnosis of character is to determine whether a particular trait in a person is fundamental (real) or compensatory (assumed).

Compensatory traits cover feelings of inferiority or of insufficiency. Compensations are to hide tendencies of an opposite nature; this being a selfdefense mechanism. Most normal people feel the need of developing selfrespect, and of acquiring social esteem.

The sex forces, if properly handled, can become the most constructive in an individual's personality. However, they can be the most insidiously destructive, if not managed properly. A person having a feeling of sex inferiority, whether organic (like the masculine woman), or functional (as eroticism) is continually striving for selfprotection. An unsuccessful striving may be the determining factor in causing a neurosis. In an ethical youth, morbid fear of erotic feelings or dreams is a not infrequent cause of intractable insomnia.

A person may inhibit the ideas of sex, but not the energy. People with much unutilized or unsublimated sex energy (tension) react to most sex situations more than one normally should. The man or woman with no sex difficulty whatever (particularly affective), will usually remain free from a neurosis. It is quite difficult for most people (excepting ascetics and philosophers) to sublimate all sex energy completely and entirely, and at the same time remain free from physiological tensions. Often those suffering from sex conflicts show a general loss of interest and are much preoccupied. If later they take a spontaneous interest in the environment and current events, this means that they have overcome their difficulties. This is of good prognostic omen.

Many people are quite willing to admit energy in connection with the selfpreservative instinct, yet loath to do so in regard to the racepreservative instinct. And yet when we compare our easy life with that of former centuries, selfpreservation is a much simpler matter now. And so much of the selfpreservative energy is utilized in pleasing the senses (including

sexuality. Sexuality is not equivalent to sensuality; but includes all that is embraced by the word "love"). To make matters more difficult, the allurements of civilization tend to increase and stimulate sexual energy. At the same time, culture markedly represses its expression. (True, eroticism is much disguised by culture, and the attempt is made to socialize much of this energy.) So in many instances, with overproduction and overrepression, there is a failure of socialization, and a neurosis results. With the neurosis, the patient falls back to the infantile (sensuous) level.

It might be said that the average person reacts to sex either prudishly or vulgarly. It is this instinct that is most tabooed, and the one that is least understood. So because of the greater repression of everything pertaining to this phase of life, it is more distorted than any other. A proper appreciation of the sex factor in the causation of the neuroses would make us understand them better. Then, for example, one would have a better understanding of the *raison d'etre* of many climacteric neuroses—instead of studying them only as vague doubtful endocrinological disorders. To stress only the physical etiological factors in the neuroses, and to neglect psychogenesis is a grave mistake. This is selfevident if you admit the neuroses are disorders at the psychological level. This is particularly easy to study in children —where phantasying and imaginations show their close connection to the neurosis.

There is a saying that many people are ethically and socially normal, but sexuality remains their weak point. But a person abnormal socially and ethically is regularly abnormal sexually. Sexually abnormal people may remain comfortable as long as they avoid comparison with sexually normal people.

Now let us review briefly the psychosexual life of the child. From birth, it is selfcentred. As it grows older, it is animistic, e. g., it invests its toys with life, etc. Being egoistic the young child never sees its own shortcomings. It feels contented and safe within the family circle, but unsafe or fearful outside of it. This early family situation must be studied carefully. For in the neuroses, before the patient can fully understand himself, he must first learn his family romance.

Naturally the infant has yet acquired no idea of morals—nor has it any idea of personal nor of property rights. (When we see this egocentricity in a hysteric, it shows a failure of psychogenesis.)

The young child has much to forget, because of later social needs. By a continued process of constantly repressing its primitive tendencies, it gradually becomes a miniature socialized being, by the time it reaches the age of five, or thereabouts.

During the development of the young child, its wishes and the wishes of its social environment conflict. But of course, social success is necessary for culture. (Where the process is taken too seriously, a neurosis may ensue.) Most of this early period is repressed into the unconscious, hence our later amnesia for these years. After the age of five, the refined child will only satisfy any asocial trends by phantasying them, or performing the acts symbolically, instead of executing the acts directly. To do otherwise would produce nervous symptoms, because of the conflict.

It is well to remember that an essential feature in a neurosis is the shame felt in regard to the asocial activity of an organ or function. The neurosis results from the conflict between the patient's ideal self and his hidden, asocial tendencies. Afterwards the patient feels fearful, angry, ashamed, embarrassed, but he refuses to admit this, and merely complains of feeling nervous or worried. Selfaccusatory ideas in a youth often have masturbation as a basis; with such as he we see preoccupation, loss of interest, or depression. He does not accuse himself directly of this act, but usually of something else. This type of reaction is more apt to be seen where the youth has received severe censure from a parent. Of course, bad traits must be corrected; for if they get beyond control they will cause a bad personality. But constructive, sympathetic help is needed; not censure. In these cases the physical results are exaggerated; the real sequelæ are psychic. Boys and girls with otherwise good traits are easily cured if properly handled. Severe punishment cures no habit; it merely causes resentment.

The ultimate end of sex is pleasure, not merely physical, but affective. In refined human beings, the affective is the more important of the two. In the child, of course, pleasure is psychologically a less complex feeling. The infant is normally interested in his own body, because of its curiosity instinct (i. e., is autoerotic. This term is not limited to the sex phase, but applies to interests in the whole body). There are some adults who never get past this stage.

Without going into the psychogenesis of the sexual impulse in detail, it is well to remember that after the autoerotic stage comes the narcissistic stage. Next we observe that the child's chief interests and likes centre about the family. From late childhood to puberty, the boy—and somewhat similarly the girl—develops extrafamilial interests. He forms close friendships and attachments for other boys. At about the time of puberty, he first becomes interested in the opposite sex. These attachments, we are considering chiefly in regard to their affective (emotional) aspect.

Now, if the child is faultily brought up, development may be retarded at any of these stages and there become more or less permanently fixed. In such cases, there is an arrest or even a failure of interest, to go on in the normal way. The results are character defects.

Of course all children have a sexual instinct. But no observer believes that this instinct suddenly flowers at puberty; rather that it passes through a gradual and progressive development. Sex in the child (in its affects, aims, expressions, etc.) is an entirely different proposition as compared to sex in the adult. The young child knows nothing of sex in the adult sense.

The young child knows of sex only in terms of the excretory functions, and it knows of these because of its natural curiosity instinct. While this type of sexual curiosity in the child must be refined, it is not necessary to ruin the child in doing so. You cannot eradicate phylogenetic influences completely, although they can be sublimated.

All parents without doubt have noticed these excretory interests, so characteristic of young children. And it is necessary for the parents to repress them,

else they are apt to become the basis for certain abnormal traits in later life; e. g., abnormal reactions of disgust, frigidity, etc. All parents manage this problem differently; some with tact, others with intense loathing, and others with too much ceremony. Young children derive an affective satisfaction in reacting to physiological needs—social culture not yet having gained the upper hand in repressing such gratifications.

We all know how very young children like to show their power. (Even some adults never give up some of their infantile ways of showing power.) It is safe to assert that desire for safety and for power are the motives back of much that the young child does. And in later life, it is also fair to assume that the guiding idea in the desire of the sick adult to secure the confidence of the physician or the clergyman, is his desire to secure safety and power in their different phases. Where a neurotic fails to secure this, it may mean psychic death (failure), expressed in terms of morbid fear.

In older children (ten to seventeen years), it is well to keep in mind that their phantasies—often not clearly crystallized—have a tendency to converge on the pelvis. For the phantasies of the period of puberty, as a rule, belong to the adult, and not to the infantile type. And misunderstood feelings in the child at this time may cause dread and apprehension. Sensitiveness is often marked. This trait, however, is only pathological when its consequences are incapacitating or destructive to the individual.

Sex undergoes marked repression in all children from infancy, but repression is greater in girls than it is in boys. So it is said, therefore, that in this sphere girls must be more on their guard than boys. The proof of this is remarkably well shown in the mental upsets of later life. In the psychoses, we quite regularly notice that men practically never hallucinate normal sex phenomena; whereas, in psychotic women, the converse of this is true. The reason for this antithesis lies in the fact that sex conflicts more with the ideals and with the main personality trends of women than it does with those of men—so that with the former, conscious gratification is out of the question.

It is quite well recognized that exaggerated sex repressions prevent many girls from ever falling in love and marrying—this in spite of the fact that there may be a conscious liking for some man. But the driving force to enter matrimony is absent. If they do marry, it is not because the race preservative instinct is so strong; their reasons are more apt to be practical. And marriage to them is often a burden or a bore. For it is quite evident that a person cannot get pleasure from an external action or situation, unless the act or situation causes satisfaction within. Girls who are autoerotic, or at least who never progress beyond the adolescent stage, usually have only a superficial interest in children. They often have a cynical regard for love.

Where a growing person's energy, interest, and attachment linger (more or less completely) at a certain stage of development—as on self, family, etc.—we refer to this as a fixation. Now fixation interferes with the development of normal adult characteristics. These fixations are especially common in neurotic children.

Without doubt, the most important lesson to learn in child psychology is to bring up the child so that at the end of adolescence (twenty-one to twenty-two years), the child will affectively (emotionally) emancipate itself from the family. For all students of this subject are agreed that a failure for the child to emancipate itself from the parent is an infantile reaction on the part of the child.

The affective attachment to the mother is in many cases so abnormally intense, that it makes the person dependent on and bound to the family circle—to the exclusion of those outside interests that make for progress. One can understand how a marked fixation on the family spoils for larger sociability, and narrows the interest in the world of reality. The normal person gets away from this infantile attitude. (It is needless to say that we are referring to abnormally close family attachments; the sort that keeps one from having any real interest in the outside world; and not to normal family love—which is an incentive for one to be interested in the world at large.)

White asserts that the strength of the undue attachment to the family circle, particularly if egoistic, is a measure of the failure for character to develop. Complete dependence is equivalent to social failure and uselessness; to say the least, it is deforming to the personality. There are instances where an excess of misapplied love for a child has done more harm than a slight lack of consideration. We all know that abnormally petted children in later life long only for the lesser world of the family circle; the outside world means nothing to them. Thus their energy becomes locked up, and unavailable for useful work.

Failure to free oneself affectively is often seen, for example, at the time of marriage. The separation from the family becomes unbearable and a neurosis results. The patient and the family, of course, always blame other factors for the nervous upset. If such marriages do not turn out badly, at best they are usually only negatively successful.

Unfortunately, parents only see the good side of this undue family fixation, which persists after adolescence. They fail to observe (or will not see) its destructive influence, as an asocial relationship on the personality.

A parent's attitude exerts a much more powerful influence in producing this fixation than any words he or she may use. For a parent's unconscious emotional hold, much more than any conscious efforts of that parent, is the deciding factor in the child's reactions. If the influence interferes with the child's biological destiny, it may destroy the personality of the child. A parent may do harm where he or she means to do good; e. g., a mother who babies her son does not realize the harm she is doing—that in continuing this course after adolescence, she thus causes him to lose his needed manly aggressiveness.

It is not rare for a boy with a fixation on a widowed mother to become a failure if she remarries. The reason for this is his inability to find another suitable object for his affections. Or the son of a lonesome or unhappily married woman, who has a very strong affective attachment to her, becomes so conditioned by this emotional attitude as he grows older, that if he ever should marry, he chooses a woman who is more of a mother to him than a wife.

The age is not important; the girl's traits are the determining factors.

A child's love interests must be thought of in terms of feeling. The person, who as an adolescent had a pronounced fixation on one or both of its parents, is very likely to be an unsatisfactory partner on marrying. (Particularly so in the case of only children who have been overcoddled and badly trained throughout childhood.) If in addition, the parents are blind to the real situation, or to their social duty, and foster this fixation even after marriage, trouble almost invariably ensues to the married couple. (Feelings of lonesomeness, dysharmonies, wishes for freedom—or a neurosis—are common sequelæ.) At best, such individuals make mediocre partners.

A growing girl may devote herself to her mother assiduously, and continually repress her cravings for motherhood. Later in life, in the thirties or forties, when there is a partial failure of this repression, she is likely to develop a neurosis.

A few more words about the psychology of the family situation might be of value. Nervous types very readily absorb the home difficulties. Bad conditions, to say nothing of the general atmosphere, in unhappy homes favor maladjustments in later life. This is a more direct explanation than the more circuitous hereditary route. Where a neurosis develops, it is in great part due to the characteristic emotional influences of the parent or parents on the child. There is nothing truer than the fact that the child is a great and consistent imitator of its parents or guardians.

It is axiomatic that in every neurosis and psychosis, another member of the family is involved, usually as a repressive influence. So it is very important that the physician should carefully study the family situation in all of these cases.

The acts of the family have great social value. The child's idea of his family is frequently at variance with the idea that the neighbors have of his family. The good manners of some families (and sometimes their ethics and their morals) are not uncommonly assumed, being a compensation, to produce a good general or public impression.

All parents do not have the same regard for all of their children; nor do they treat them all alike. Especially is this so, if one (or more) has resulted from an unwished for or unwelcome impregnation: not a rare occurrence.

Parents who have as prominent traits, selfishness, extreme touchiness, prudery, or hatred, can hardly expect to rear children with normal traits and trends.

One can easily picture the difficulty where a neurotic patient, with sex as an evident factor, has to depend for assistance on a parent whose chief trait is excessive prudery. And one must distinguish between goodness as a real trait, and prudishness as a compensatory trait. In the instance just mentioned, sympathy may be given out of the mouth, but not from the heart. Verbal sympathy and affective sympathy are not the same.

Our fate really depends on our early family affections. A child's first loves and first hates relate to those in the family circle. (Clearly seen in psychotic upsets.) Family feuds are often very intensive and constitute a great hindrance to the proper management of a nervous patient in such a family.

We hear a great deal of the child parent love, but very little of the child parent antipathy, resentment—even hatred. The latter is repressed but it leaves its effect, and is often the chief etiological factor in a later neurosis.

The cravings of the young child demand that its love be returned. Where it is not returned, the child feels resentment. But even then, because of the ambivalency of feelings, the child still loves the parent against whom he is antagonistic.

A father, though he be otherwise good and thoughtful, may spoil individuality in his growing son by unnecessary or harsh domination. It might be said here that many men who devote most of their time to creative thinking, are not practical fathers.

It is well to remember that there are two extreme ways of training a child. One is with excessive love and coddling; which causes dependence and weakness of character. The other is with a lack or absence of love, and too great severity, which causes chronic dissatisfaction and discontent, a turning inward of the child's feelings, antagonism, etc. One must avoid either extreme—of giving absolute freedom, or of completely dominating the child.

Children who are unduly subdued, lack initiative and natural curiosity, which are normal characteristics of the child. Such a child in later life is apt to be interested in him—or herself. If the psychic development never gets beyond the adolescent attitude, such a one is disinclined to marry; or marriage may be entered into rather cynically. Such types have only a superficial interest in rearing children.

One might put this in another way and say that an oversubdued male is apt to remain autoerotic, or take an interest only in the endeavors and pursuits of man. If he marries, his heterosexual attitude being weak, he soon regresses to the easier adolescent level. (A psychic and not a physical regression is the rule.) He may have a plus social, but a minus love interest in women.

Many children are incidentally brought up, instead of being guided along, as far as any intelligent attempt to develop character is concerned.

The parent should realize that to harshly taboo every normal interest in sex in the growing child favors secret vulgarity or prudishness; and it also drives the child from the parents or guardians to improper sources to satisfy its curiosity. The wise mother with her magnificent emotional hold on the child can divert the interest in sex to other estimable paths. To free a child from sex difficulties, it is not enough merely to try to talk the interest in sex away, nor, worse still, to severely censure the child. Sympathy and the substitution of approved healthy activities to use up the energy is what is desirable.

It is really a bad mistake on the part of the parents to try to inculcate ideas that everything relating to sex is shameful or degrading. This will only condition the child to react to sex, even after marriage, with dislike, disgust, or shame, and in this way jeopardize the happiness of married life.

The parent's love for the child should be altruistic, not selfish. Real culture demands that the child should be reared for its own welfare, and not for the pleasure nor profit of the family.

The repression necessary to refine the young child must not be overdone. And it must be accompanied

by social substitutes for the expression of his energy, if he is later to become a normal social being. For excessive repression, with a failure to socialize sex energy, is sure to cause bad character trends (autoeroticism, narcissism, etc.) in the child. A similar failure of socialization in the sphere of hunger, produces the various types of the glutton. In training the youth, your aim must be sublimation. (A term borrowed from chemistry, meaning to refine.) No advice not in accord with normal ethical standards, nor which is against the dictates of medical dignity, is permissible. One must remember the social obligations of the profession.

It is not hard to see how an ethical individual with an erotic disposition, will find it difficult on recovering from a neurosis to remain comfortable, unless the family furnishes acceptable outlets for the sublimation of his or her energy. The aim of sublimation is to direct sexual and asocial cravings into socially approved channels. It is not meant to allow the energy to be wasted, nor to annihilate the sex affections. Thus the cure of masturbation is along these lines; at the same time inculcating a fine moral tone in the young individual. This is quite different from harsh criticisms, making false and unscientific prophesies about resulting insanity, chronic invalidism, etc.

The degree of sublimation depends on the strength of the good traits inculculated in the first few years of life. The means used are numerous; study, devout prayer, invigorating play, and pleasant work. All of these help to elevate the emotions, and to direct them to a more useful goal. Fostering an interest in music, art, literature, friends, hobbies, etc., is valuable.

So in general, one can say that the two aims in managing these cases of sex difficulties are, to diminish the strength of the cravings, and to increase the number and quality of good social outlets.

In concluding, I would like to emphasize the value of the study of the psychosexual life of the child. Child study in its social aspects has long occupied the minds of our best students. But this was not always so. It may surprise many to learn that in the United States there was a society for the prevention of cruelty to animals (1823) before the first society for the prevention of cruelty to children was founded (1874).

Psychopathologists, today, are giving close attention to the study of the child's psyche. And with a fuller knowledge of psychogenesis in the child, one can better understand the sex interests and problems of the child and youth. In many of these difficulties, the psychic factors are extremely more important than the physical ones. Certainly it will be admitted that the absence of happiness in a nervous individual is clinically of more importance than the presence of a dermatographia or an indicanuria. So for such reasons, we must fathom the real underlying causes of nervous disturbances. Superficial explanations are usually only deceptions. The task is a difficult one; but the results obtained will repay your intensive study in every instance.

92 Gates Avenue.

The Work of the New York Psychiatric Society*

SMITH ELY JELLIFFE, M.D.,
New York

I wish to call attention to some of the matters that have received our consideration as an evidence of what we have stood for in the past two years.

While we may be able to record upon the printed page some index of our scientific programs, it is not possible to transcribe the results of the work done by you in committee which has been of such signal service to the success of our meetings and which have given this society a prestige of which we are little aware. The splendid work of Russell as chairman of our legislative committee, of Dana, as chairman of more than one committee, not to mention others, has been of much material service to your president, for which he would at this time extend his sincerest thanks.

In calling attention to our scientific programs, I shall not at this time make any effort at completeness; I shall only take up a few of the contributions to our field which I believe are worthy of accent. In so emphasizing these few features I would not mean that others were not of equal value. Inasmuch as I cannot review all of this work, my selection has been difficult, and to avoid any invidious comparisons, let us say it has been purely fortuitous.

*Address of retiring president, February, 1924.

At our first meeting in February, 1922, you did me the honor to listen to my Introductory Address on "Paleopsychology; a Suggestion Covering the Evolution of Symbolic Functioning"—in which I attempted briefly to indicate a conception in the evolution of the psychobiological sciences which might be of service in disentangling the complicated symptomatic behavioristic perplexities which surround us as psychiatrists on all sides.

That the human psyche has a history it was not necessary to point out to this society, but I did deem it pertinent to accent some features of primitive thinking which were constantly outcropping in human behavior, which by reason of their strange and bizarre character had always been of special interest to our science. I felt it profitable to look at these in some manner analogous to the outcroppings of certain paleozoological forms in the study of geology and accented the possibility of erecting a new subdivision of our science which might envisage all of these archaic and strange remnants of the more primitive stages of the laying down of the human ego. I might at this time not unprofitably call your attention to the more recent work of Lévy Bruhl on *Primitive Mentality*, and of Storch, on *Archaic*

Activities and Thinking in Schizophrenia as bearing directly upon this topic.

This meeting also dealt with some important features of the manic depressive psychoses. Kirby outlined the rich clinical picture, Clark and Amsdem spoke of the personality trends, Gregory touched upon a number of interesting clinical situations, Cotton showed how the hypermotility was registerable on x ray plate and your president accented what even mere recent investigation has shown, that unconscious homoerotic factors play a large part in determining the special picture in a great number of this general group of cases. In the terms of his opening address, here was a situation which phyletically considered was in part conditioned by the persistence in the unconscious cravings of as yet unsocialized adaptations of a more primitive type of object attraction. Here was a situation which in terms of archaic symbolizations the ancient Hebrew theologists had called "blasphemy to God" and had described, as historical, the destruction of Sodom and Gomorrah which was but a mythical, or primitive mentality form of presentation of these still present failures in social evolution.

In our March meeting we were fortunate in obtaining some insight into the significance of the dynamic forces operative under the disguise of what we call dementia precox: L. Nolan Lewis, of St. Elizabeth's, in Washington, brought before us the rich material of that leading institute in the United States. He showed us how the body as a whole was involved in the dementia precox reaction. In a highly instructive manner documented upon pathological material that said but one thing, he showed us the numerous aplasias, or defective developmental changes that were present throughout the entire body. Small hearts, small aortas, small arteries, apalsic endocrines. Here were widespread defects that showed up the dementia precox reaction types in a much more comprehensive manner than had been our habit to see them. We were unfortunate that sickness prevented him from developing a related group of observations concerning the paranoid persecutory reaction types in whom the high tension of compensatory strivings had built up an entirely different somatic picture.

Of a related behavioristic personality type, L. Pierce Clark developed for us some further considerations concerning the nature of the consciousness of the epileptic. Your president in his opening address laid before you the general proposition that mentality types could be advantageously studied in terms of gradation from upper to lower forms. Your knowledge of the mental frames of the idiot and imbecile which in a general way can be studied advantageously along lines of animal behavior, makes it all the more readily conceivable that the less severe grades of personality disintegrations are capable of somewhat similar differentiation. Thus Clark presented the conscious personality syndrome in the essential epileptic and discussed its nature, particularly in its faulty adaptation to social requirements and its gravely altered constitutional background.

It was my good fortune to be able to spend five months in Europe in the summer of 1921, during which time I visited the chief neuropsychiatric centres of Northern Europe, where I met many friends I had known before the war and made a number of acquaintances with the younger band of workers who had come to the fore during the seven year interval since my last visit. I took you all too hastily through this pilgrimage and sought to show by a large collection of lantern slides the chief lines of development which were going on.

The encephalitis epidemic had raged widely and in all the countries visited the returns of rare and anomalous motor and psychical symptom pictures were being analyzed. Both the Paris Neurological Reunion and the German Society of Neurologists had made these the chief topics of their discussions. I was able to show you photographs of the workers and some of the anatomical pathological findings of this greatly expanding knowledge of the amyostatic syndrome and their striopallidal correlations. The work of the Dutch school headed by Winkler, and ably supported by such men as Kappers, Brouwer, Magnus, Klein, Jelgersma, the Boltons and the Baumanns, concerning problems of comparative neurology, of decerebrate rigidity, of the vegetative syndromes and newer work on the psychoses was presented.

At our meeting in November, 1922, we were fortunate in having with us Prof. W. Weygandt, of the Psychiatric Clinic at Hamburg, and he demonstrated in a clear and convincing manner that the therapeutic attack upon that nightmare of psychiatry, general paresis, was progressing by means of the new malarial treatment inaugurated by Wagner v. Jauregg at Vienna, whose results had been spoken of in the neuropsychiatric pilgrimage of which I have spoken.

Amsden of our society gave us in March of 1923 a revised guide of the Study of the Personality which some years previously he had elaborated with Hoch, and the same evening we had lantern slides from Bloomingdale Hospital regarding certain motility changes in the gastrointestinal tract, particularly in manic depressive and schizophrenic patients.

The Mental Hygiene Association and the extension of its demonstration clinics was presented by V. V. Anderson at our April meeting and in the meeting of November Dr. Campbell gave us a delightful appreciation of certain aspects of Dr. Jung's psychological studies as he had come in contact with them in the past summer in England.

Little and Potter outlined some of the work being done with the feebleminded at Letchworth Village.

Finally, at our last meeting, we had a stimulating and interesting excursion into the realms of pure logic with a demonstration of his anthropometer by Count Korbitzsky, from which some of us have not yet recovered our usual composure.

With this bare outline it may be seen that our scientific sessions have not been without some variation at all events. I trust that, as you helmsman, they led you into ports of interest and profit, for without your generous support I would not have been able to do so much. Any inadequacies of accomplishment I lay at my own door. For your generous attention I am profoundly grateful.

Segmental Cerebral Monoplegia with Jacksonian Epilepsy Due to a Subcortical Glioma*

DUER REYNOLDS, M.D.,
Kennett Square, Pa.
and GEORGE WILSON, M.D.,
Philadelphia

Paralysis of one extremity or of a part of one extremity if due to a cerebral lesion is always cortical because a lesion of the internal capsule no matter how small may be said, for practical purposes, always to produce a hemiplegia or a hemiparesis. A monoplegia or segmental monoplegia is usually due to a cerebral neoplasm although occasionally a vascular lesion produces it (1). Injuries to the brain or a cerebral abscess may bring about localized paralysis of an extremity. The history of the onset is extremely important although not entirely diagnostic; a sudden onset usually means a vascular lesion although in the case to be reported the initial symptoms were sudden in their onset and then slowly progressive.

Spiller in a recent article (2) reported four interesting cases of the condition under discussion; three of them were due to a cerebral neoplasm and the other was vascular in origin. The onset was acute in one of the cases of brain tumor.

We present the following case because of the relative infrequency of a segmental cerebral monoplegia and because the onset was of such a nature as to make the diagnosis in the early stages somewhat difficult.

Case—A white male, sixty years of age with a negative family history gave the following story of his illness: On the last Sunday in September, 1923, while walking, apparently in good health, he felt a stinging sensation on the back of the left hand, and the hand and fingers became suddenly weak. Four weeks after the onset he had a convulsion limited to the left hand and arm; in his attack the thumb was sharply adducted and the fingers flexed and after a few minutes the convulsion became a clonic one. He had three attacks within an hour. After the first convulsions the frequency was about every other day; later on he had about one fit daily until he finally had as many as six in twenty-four hours. The first spasms involved the arm and forearm but in the last few weeks only the hand was implicated.

Examination on November 5, 1923: Movements of the fingers and thumb of the left hand were practically nil. Extension and flexion of the wrist were possible but were weak. All the deep reflexes were present and normal. Pain, touch, vibration, touch localization and the sense of position were normal throughout. During the examination the man had a Jacksonian fit limited to the left hand. The attack lasted about three minutes and consisted of clonic movements in flexion and extension of the wrist and fingers.

At this time he was referred to the University Hospital where examination of the eye grounds and fields, blood, spinal fluid, urine and rontgenogram of the skull proved negative.

Clinical course and outcome: By the end of November movements of the wrist were extremely weak and pronation and supination of the hand were performed with difficulty. Flexion and extension at the elbow showed a fair preservation of power. At this time the deep reflexes on the left side of the body were increased although Babinski's sign was not obtained. Sensation remained normal. The number and severity of the Jacksonian fits had decreased. Occasionally during his stay in the hospital twitchings of the left side of the face were noted. Cerebrospinal fluid pressure was 18 mm. of mer-

cury; after compression of the jugular veins the reading on the spinal manometer was 36.

The man was referred to Dr. C. H. Frazier who performed a craniotomy exposing the right motor cortex. A large, subcortical glioma was found which was irremovable (Figs. 1, 2 and 3). The patient died two days after the operation.

COMMENT AND SUMMARY

This case presented certain diagnostic difficulties; the suddenness of the onset in a man of sixty without a preceding history suggestive of a cerebral neoplasm would naturally lead one to suspect the presence of a vascular lesion. The presence of Jacksonian epilepsy, however, pointed to an irritative lesion of the cortex and while this may occur as the result of cerebral thrombosis it is much more frequently seen in neoplasms or other irritative lesions of the cortex.

The diagnosis of cerebral neoplasm was made but operation was not advised at first. If the case improved it would make a vascular lesion almost certain whereas the progression of the symptoms would clinch the diagnosis of tumor. In a relatively short time (two or three weeks) paralysis gradually increased and the reflexes on the left side of the body became exaggerated. An operation was no longer postponed and was performed about three and a half months after the onset. It was hoped that an endothelioma would be found, but unfortunately for the man an infiltrating glioma was discovered. The general symptoms of brain tumor including choked disc were never present in this case.

It is remarkable, although quite characteristic of cerebral gliomas, that the tumor attained such great size without producing the ordinary symptoms of brain tumor, and without causing more positive physical signs. The tumor was just below the cortex and consequently involved the fibres originating from the motor cortex rather than the cortex itself.

Modern Conceptions in Hospital Psychiatric Practice

DELMER D. DURGIN, M.D.,
Central Islip, Long Island

The chief purpose of this paper is to discuss briefly methods in the care and treatment of psychiatric patients, largely along progressive lines, fully realizing that ideal conditions for its application do not at present exist. However, now that our citizens at the polls have rendered favorable decision in passing the bond issue, we may hope for better opportunities for work along more constructive therapeutic lines.

From the beginning of time we have mention of the distress and difficulty of mental derangements, but it is not my intention to go back or review from the Garden of Eden period (for Cain is said to have grown jealous of Abel's success, and knowing this it is logical to infer from the nature of his act he was deranged) to the present day, but rather to accept the therapy used in the past as good and in keeping with the teaching of its time.

The practice of medicine today is becoming more and more specialized. Thus, in the branch of psychiatry with the present day conception of twenty-one types of illnesses, why would it not be wise to classify patients more strictly according to diagnosis, and produce specialists in manic depressive insanity, dementia precox, general paralysis, and other conditions, the patients receiving the benefit of such specialized treatment.

Outside of syphilitic disorders and a few clear cut toxic illnesses, we are not yet overwise as to the cause of mental derangement, thus making it very difficult to direct the treatment other than in a gun-shot type of manner with the hope of hitting right. In illnesses where the cause is not clear our efforts must be to determine if the body is normal and functioning properly, with the idea of making it so, as nearly as possible, if found otherwise. A searching physical examination should be started at once, making use of every test to find and eliminate possible trouble.

More attention should be given to the abdominal conditions, particularly the presence of malformations of the intestines, the rapidity or retardation in their action, and perhaps we may find a toxemia that can be relieved with curative results. The x ray should be in more universal use to ascertain the condition of internal organs, so that where indicated selective surgery may be performed. Make a study of the external secretions as well as the internal, which are attracting such wide attention, and determine if possible if any are offending either by omission or commission, for it is only along these lines that we can hope to progress and help the patient.

Dental work has come into its own of late, and while I do not advocate wholesale extractions, yet it is certain that more attention can well be paid to the teeth, getting rid of foci of infection here, as in other parts of the body, not only putting the mouth in a healthy state but supplying teeth so that food will be properly masticated.

In many toxic disorders and excitements patients often do remarkably well under treatment in continuous baths, while the depressed inactive states require a more stimulating measure, such as hot and cold sprays, etc. In dropsical conditions, steam baths often help reduce edema, and through cutaneous elimination aid in relieving the burden carried by the cardiovascular renal system with marked comfort and ease to the patient.

There is division in the ranks regarding the value of psychoanalysis; it has strong advocates and those who are, to say the least, only lukewarm about it.

Perhaps the subject can best be disposed of by granting equal rights, letting those favor it who choose, and vice versa. At any rate if actual benefits and results are obtained by its use, it certainly is to be recommended. If in bringing to consciousness hidden conflicts that are causing mental illness a normal healthy adjustment can be effected, naught can justly be said against it, and we all should be for it; but to let a person know his trouble without ridding him of it or shifting its location is of little worth. In like manner, as open confession is good for the soul, so should psychoanalysis be for the troubled mind; though it is not applicable or needed as a routine measure, yet in certain well selected cases there is little doubt that it has great value and should be used.

Whether one chooses to practise psychoanalysis or not, I think all must admit that it is worth understanding that we may better size up our cases and in many instances without going into the depths of the thing be better able to advise the patient wisely.

Our patient having run the gauntlet of medicine and surgery, become acquainted with Volsteadism, taken his dose of mental catharsis, either knowing about or getting rid of his complexes, and is found physically fit, he is now ready to go to work. In the hospital we term it occupational therapy, which is something of routine value and should be given in more liberal doses. Even while the mind is warped, with a healthy body much can be accomplished. When the patient is at work his attention becomes centred upon what is being done and directed away from his troubles, which if not curative will greatly lessen the irritation and improve conduct. This conduct disorder problem is no small matter, for it disturbs the hospital population equally as much as it does in outside life, though in our case there is no recourse to law or discipline, being entirely a matter of treatment, for the irresponsible cannot be held accountable for their acts.

In general it is well to remember that for depressions we use work calling for thought concentration; for the disturbed, a more monotonous task; for the erratic, a work calling for more sustained effort and application; for the indifferent, where comes the real task, try more stimulating processes, with frequent changes and variety to arouse interest. A carefully arranged system of promotions as the patients improve under training must be maintained, along with systematized recreational hours as a stimulus for effort, and eventually help the patient along the line towards home or at least to be of aid in hospital productive industry.

It therefore becomes our duty to work along progressive lines, making use of every phase of therapy adaptable to the case that carries even hopes of bringing about complete or partial results. Complete restoration to health in those mentally ill would be ideal but unfortunately with our present knowledge this is impossible; however, there is much that can be accomplished towards partial results, for if we can direct those with troubled mind to continued usefulness the burden of care and maintenance will be greatly lessened, and the individual healthier and happier in leading what at least approaches a normal existence and selfrespect.

An Unusual Case of Sensory Disturbance of the Rectum Following Operation

ARTHUR A. LANDSMAN, M.D.,
New York

Case.—V. H., male, clerk, single, fifty-three years of age. His venereal history was negative, previous and personal history were irrelevant. He presented himself at the rectal clinic with a complaint dating back nine months, which began with an irritation and sense of discomfort about the rectum unrelated to defecation. The bowels moved daily, there was no bleeding, discharge or protrusion. He consulted an advertising doctor, who made a diagnosis of hemorrhoids and promised to cure him by operation to be done under local anesthesia which would only lay him up over night. To this the patient submitted, and left for his home the next morning. Rectal hemorrhage followed for which it was necessary to call a physician. He suffered from chills, fever, diarrhea, tenesmus and weakness, and stayed in bed eleven days before his symptoms subsided, when he was pronounced cured of piles. But there developed a most distressing sensation of cold in the rectum, which radiated to the buttocks and thighs, increased in degree when he expelled flatus, and felt, according to his description, like the passage of an icy blast through the bowel. This persisted with only slight remissions since his operation and made him feel miserable, depriving him of rest and preventing him from concentrating on his work. He found it hard to move the bowels, felt distended, and complained of abdominal pains. Examination showed hyperesthesia of the skin about the anus, inner side of buttocks and thighs, but no disturbance of the temperature sense or deep reflexes. Urine, blood and feces were negative. Inspection of the rectum disclosed a firm, annular stricture two and one half cm. from the anus, thickening of the rectal walls and erosions and ulcerations of the mucous membrane.

Sensory disturbances of the lower bowel are not uncommon in chronic proctitis and other pathological rectal states, and sometimes follow operations when there has been much trauma or infection of the parts. They take the form of numbness, tingling and hyperesthesia of the region of the coccyx especially upon sitting, but are usually temporary and pass off when the divided nerves have become regenerated and scar tissue softened. The case reported here is an unusual form of paresthesia secondary to operation complicated by stricture of the rectum.

The Adrenal Cortex and Medulla in Respiration Versus the Bane of Medical Progress, the Diffusion Doctrine of Physiologists

CHARLES E. de M. SAJOUS, M.D., LL.D., Sc.D.,
Philadelphia,
Professor of Applied Endocrinology, University of Pennsylvania Graduate School of Medicine

It would be difficult to find in the whole realm of human thought a more imperative need than that of establishing on a sound basis the function of respiration, meaning thereby both pulmonary respiration and tissue oxidation. Although the diffusion doctrine satisfies most physiologists, being still taught in our medical schools, those of us who minister to the sick and who need to fathom morbid states to improve our means of relief, find in this doctrine nothing but disappointment. The reasons for this will now be adduced and the elements of a different and more helpful interpretation submitted.

DIFFUSION DOCTRINE

The fallaciousness of this doctrine asserts itself on all sides. It fails utterly to explain the respiratory ratio. As far back as 1905, C. R. Barnes (1), professor of plant physiology in the University of Chicago, wrote, after examining the best of our textbooks: "The respiratory ratio has proved a veritable will-o'-the-wisp, leading investigators into a bog where their labors and their thinking were alike futile. For, as a sign of what is going on within, the respiratory quotient is absolutely valueless." A distinguished English physiologist, Leonard Hill, also wrote soon after (1906): "It is impossible to give a satisfactory account of the gaseous exchange between the blood and the alveolar air." Its present status is well shown by the statement of an editorial writer in the *Journal of the American Medical Association* of June 7, 1919, that "an answer to the question as to how the all important oxidations in the body are brought about is almost as obscure today as it was a hundred years ago." As to its bearing on pathogenesis, Halliburton wrote in the last edition of his textbook of physiology (1921) that "knowledge of tissue respiration is so scanty that we can say but little about its pathological bearing."

Practitioners in all fields of medical work must fail to realize what this means to the welfare of those who entrust their lives to them; otherwise they would urge physiologists to turn aside from a theory which, from its very incipiency has only afforded an obstacle to medical progress incomparably greater than any that could be devised. I have submitted elsewhere (2) that it has kept from pathologists, owing to its identity as a fundamental function, the pathogenesis of even such commonplace phenomena as fever, hyperthermia, autolysis, the death dealing gamut of infectious diseases, over one hundred strong. The cardiovascular diseases, exceeding in death rate all others nowadays, can all be traced originally to perversions of nutritional oxidations. This applies as well to cancer and, in fact, to the entire range of pathogenicity. Psychiatry and the general neuroses have suffered as much as any other branch of medical knowledge. How could they thrive as far as the organic side of nervous disorders is concerned when the very *deus ex machina,* the nature of the nerve impulse, remains unknown?

In truth, the diffusion doctrine has been under fire ever since 1856 owing in part to the discordant data afforded by instrumental methods. Armand Gautier, professor of physiology in the Paris Medical Faculty, over thirty years ago, deemed it wrong for physiologists to continue to see in the respiratory phenomena but mere results of diffusion of gases through inert membranes. Indeed, many discrepancies besides those of instrumental origin have branded the theory as unsound. Why, for instance, disregard Paul Bert's (3) observation that the absorption of oxygen by the pulmonary blood persists when the pressure of this gas is almost *nil;* or Müller's that a strangulated animal exhausts the air in its lungs of all its oxygen; or those of Setschenow and Holmgren (4), Zuntz (5) and others, who found only traces of oxygen in the arterial blood of asphyxiated animals?

Evidence has steadily accumulated in recent years also to the effect that the oxygen tension in the arterial blood can be considerably higher than in the alveolar air. This was frequently noted by the Anglo-American Expedition to Pike's Peak in 1911, and also by the Mount Everest Expedition which, as stated by Haldane (6), "bore out the oxygen secretion theory," advanced by Professor Bohr, of Copenhagen, in 1891 and sustained by Haldane, Vaughn, Lorrain Smith, the Oxford School and others, which

attributed to the lungs the power of clutching oxygen from the air in the alveoli and to force it into the blood.

The perpetuation of the diffusion doctrine in the face of all these invalidating facts was due, however, to an essential feature of the whole problem, i. e., the inability of the physiologists to identify the nature of the secretion capable of carrying on this function.

ADRENAL MEDULLA IN RESPIRATION AND TISSUE OXIDATION

In 1903 (7) I submitted on the basis of much evidence, that the secretion of the adrenals supplied the needs of the respiratory process. Since then this view has been confirmed even to its details:

1. There can be no doubt that adrenalin influences actively the respiratory process. Bernstein and Falta (8), Nice, Rock and Courtright (9), Tompkins, Sturgis and Wearn (10), Sandiford (11) and others, found that it increased the intake of oxygen, the output of carbon dioxide, the volume of air breathed, the respiratory excursions of the lungs and the depth and rate of respiration. While Januschke and Pollak (12) noted that injections of adrenin in doses of one tenth mg. (one six hundredth grain) caused an increase of the respiratory excursions of the lungs, thus showing the minuteness of the quantity of the medullar principle needed to carry on the respiratory process. Nice, Rock, and Courtright also demonstrated its independence from the vascular tension when they found that adrenalin, whether injected in minute doses, causing a fall of blood pressure or in large doses, causing a rise of blood pressure, evoked an increase in the depth of the respiration.

2. Nor can there be any doubt that the process occurs in the lungs and that the adrenal secretion converts hemoglobin into oxyhemoglobin. Adrenalin was found by D. E. Jackson (13) to produce prompt dilatation of the bronchioles when these were contracted, quite independently of any rise of blood pressure, while W. E. Dixon (14) ascertained that it facilitated the free circulation of the air in the alveoli by causing the dilatation of the bronchioles referred to. Even the conversion of the venous blood into arterial blood by the adrenal product has been found to be true. Thus, Menten (15) having added adrenalin to diluted human venous blood, found that it caused an increase in the intensity of the oxyhemoglobin absorption bands. The similarity between the spectra of adrenal vein blood and those obtained from venous blood to which adrenalin was added was emphasized, Menten remarking that it afforded "unquestionably very strong evidence that it is adrenalin which is responsible for the increased amount of oxyhemoglobin that is found in the adrenal vein blood."

That this applies to the circulating blood as well was shown by the fact that adrenalin was also found in the blood and red corpuscles by Battelli (16) and Mulon (17). I had urged that the adrenal product which I termed adrenoxidase, acted as a catalyst (oxydase-catalase) in all oxidation processes. R. G. Hoskins (18) stated recently that "the disproportion between the quantity involved and the effect produced, as well as direct experimentation, indicates that adrenalin serves to catalyze some reaction in the process of fuel oxidation. It is probable that the intervention is in the immediate oxidation reactions; that is, that the substance serves as a respiratory catalyst."

3. That, as I also urged in 1903, "the oxidizing constituent of the hemoglobin sustains tissue oxidation and metabolism" has likewise been sustained by many observers. Adrenal extracts had long been known to raise the temperature and accelerate metabolism simultaneously. More recently, Sandiford (11) found in seventy-three experiments in endocrine patients that seven and a half minims of adrenalin invariably raised the basal metabolic rate. This was preceded by a rise in the respiratory quotient, according to Tompkins, Sturgis and Wearn (10) thus showing clearly a connection between the two processes, while it proved inexplicable, as stated by Boothby and Sandiford (19), by a mobilization of glucose. Large adrenal grafts may cause so great a rise of temperature as sometimes to cause death, as observed by Jaboulay (20) and others. Malignant adrenal growths, regardless of histological structure, may also, according to Israel (21), run a febrile course independent of any fever producing complications. The rise of temperature can be produced, however, by doses of adrenin within the powers of the adrenals to secrete (22). Accelerated metabolism was also shown by Tompkins, Sturgis and Wearn (10) when used in not too great doses (vasoinhibitory) or too small (inadequate) doses and, according to Addis, Barnett and Shevky (23), to be accompanied by an increased excretion of urea.

It might be urged that all these phenomena are purely pharmacological, i. e., caused by the adrenal preparations acting as drugs. That this is not true, however, and that all the respiratory and metabolic phenomena produced by adrenin (meaning thereby the secretion of the medulla of which epinephrin or adrenalin is the active principle) represent exacerbations of a corresponding function is shown by the fact that removal of the adrenals evokes contrary effects. Thus, Brown-Séquard and many physiologists since have noted a decline of temperature in animals deprived of their adrenals; it is also a leading symptom in Addison's disease along with those of slowed metabolism. The basal metabolic rate in adrenalectomized cats, carefully controlled by Aub, Forman and Bright (24), showed a reduction of twenty-five per cent., while the same operation in rabbits was found by Bevier and Shevky (25) to cause a depression of the excretion of urea.

Such perfect balance between the effects of adrenin on the one hand and the results of removal on the other, shows clearly that we are dealing with a physiological function of adrenin, while the influence of the latter on metabolism indicates that it is a dominant factor in tissue respiration.

A suggestive fact must now be emphasized, i. e., that the few physiologists who give special attention to the ductless glands (the many who do not merely adopting the opinions of their endocrinological colleagues) have failed to bring to light the functions of the adrenals. Swale Vincent (26), professor of physiology at the University of London, for instance, concluded as late as 1922 that "the adrenal medulla appears to be of no importance, the functions of the adrenals being probably wrapped up in the cortex."

while as late as March, 1924, R. G. Hoskins (18), professor of physiology at the Ohio State University, also wrote concerning these organs: "Despite a very large body of careful observations, these organs remain a mystifying puzzle." If this be true, all the immense labor devoted to the adrenals recorded by workers in all branches of medical science, pure and applied, since 1849, when Addison described the disease which bears his name, has remained sterile. So unthinkable a record can only be explained in one way in the light of the data submitted: physiologists did not take into account the direct connection between the adrenals and respiration and failed in every other direction.

ADRENAL CORTEX IN TISSUE OXIDATION

The functions of the cortex are deemed unknown by the physiologists, we have seen, even though this structure is regarded by them as probably the active portion of the adrenals. Indeed, its essential rôle in the vital processes is clearly shown: by the fatal effects of its removal unless supplemented by accessory organs, as in the rat; by its increase in size during pregnancy; by its great size during infancy and development; by its direct connection with the gonads and the phenomena of puberty and secondary sex characters; by its remarkable stimulation, when the seat of certain tumors, of growth; by its remarkable tendency to undergo degenerative changes after burns, venoms, the administration of certain poisons, and other conditions.

The personal view that the cortex cooperates with the medulla in carrying on tissue oxidation, was only reached last year (1923) after a comprehensive study of the lipoids, long known to be important features of the chemistry of the cortex and of all tissues, and also a revision of the labors on biochemistry and functions of the leucocytes, which occupies over one hundred pages in my work on the internal secretions. In the present paper, however, I can only cite but a fraction of the evidence available—just enough to bring out the salient points of the function I attribute to the cortex.

Each adrenal is composed, as is well known, of various zones, but for our purpose it will suffice to recall that the organ consists, in man, of columns of polygonal cells directed from the outer capsule towards a common centre, as are the ribs of a palmleaf fan towards its stem. Nine tenths of these columns constitute the cortex and the remaining tenth the medulla. The latter, in turn, drains the whole organ of its blood, the terminal canal of which, typifying the stem of the fan, consists of the adrenal vein.

A striking feature of each adrenal is the relatively enormous volume of blood which passes through it, i.e., six times its weight in blood traversing the organ every minute. It is supplied by the large suprarenal arteries, which penetrate each adrenal through its external capsule and subdivide into smaller vessels, which form ultimately a very close capillary network in the cortex. The blood then passes to the wide sinuslike spaces in the medulla and finally into the adrenal veins, which carry it into the inferior vena cava.

The relation of the adrenals to the red corpuscles suggests itself when we realize that the contents of the latter is similar to that of the cortex and medulla combined and that the adrenal secretion likewise contains these bodies. Howell, in his textbook (1923) after describing the stroma and hemoglobin of the red corpuscles remarks, for instance, that "great interest attaches to the presence of the lecithin and cholesterin whether these substances are found in an external membrane or in a stroma permeating the corpuscle."

As to the adrenal cortex, it was also found to contain lecithin, a fat rich in phosphorus, by Bernard and Bigart in 1902, Mulon in 1903, and many other investigators since, while cholesterin, or better cholesterol, a monatomic alcohol, has received considerable attention in recent years as a prominent constituent of the cortex. While its presence in this structure has been shown by Elliott and Tuckett (27), Adami and Aschoff (28) and many others, Chauffard, Laroche and Grigaut (29) have gone so far as to contend that the cortex is the actual source of cholesterol, so marked are its fluctuations in this structure in pathological processes. The cortical columns are filled with these lipoids which form columnar rows of brilliant yellow cells, directed, as we have seen, toward the central medulla. As stated by Goormaghtigh (30), after examining the cortices of many soldiers killed while in normal health during the World War, the cortex appears to act as a storehouse for lipoids.

What is the origin of the lipoids in the adrenal cortex? Granting, pending further research, that the cholesterol is formed in the adrenal cortex as contended by Chauffard, Laroche and Grigaut, what is the origin of its lecithin? In 1903 (31), I included the leucocytes among the ductless glands and stated that their granules were "products of an intracellular metabolic process and represent a true secretion." Since then French investigators refer currently to leucocytes as such. Chauffard (32) for instance held recently (1923) that "the leucocyte must be considered as a true monocellular endocrine" forming in the aggregate "a multitude of ambulating laboratories." The cortex, from my viewpoint, is supplied with its lecithin by eosinophils which course through it with the large quantity of blood which traverses the organ.

The presence of lecithin in the granules of eosinophils was observed thirty years ago by Kanthack and Hardy who stressed their bright greenish lustre. Various investigators have confirmed this observation. Pappenheim (33) having ascertained that eosinophil granules were neither neutral fat nor cholesterol, Stassano and Billon (34) identified them as lecithin. That these leucocytes secrete their granulations was first pointed out by Ehrlich and his opinion has been sustained by numerous histologists. Sangree (35) and others have observed the actual extrusion of the eosinophil granules into the plasma.

The manner in which the secretory products of the cortex are merged with the medullar or chromaphil secretion cannot be discussed here owing to lack of space. All three products are found in the blood of the adrenal veins. While Gottschau, Biedl and many others have called attention to their presence therein, the proportion of cholesterol in the adrenal vein was found by Porak and Quinquaud (36) to be much greater than in the carotid, femoral and other great vessels.

Adrenin, lecithin and cholesterol being thus found in the adrenals, the adrenal veins and the red blood corpuscles, what is the relationship between these corpuscles and the three agents which constitute the adrenal secretion?

While, as we have seen, the medullary secretion, adrenin, reaches the pulmonary alveoli to become, in the presence of the air, converted into adrenoxidase, the manner in which it is conveyed to the lungs is still *sub judice,* as far as the vena cava blood is concerned. The fact, however, that Gley was unable to find adrenin in the caval blood plasma suggests that it may be absorbed in the adrenal veins by the spongy stroma of the red corpuscles, along with what lecithin and cholesterin they need to make up their deficiency in these three substances after circulating throughout the body. The red corpuscles are thus continuously kept fit to carry on their all important functions.

The rôle of adrenoxidase, lecithin and cholesterin in the tissues will require a special article. I will submit therein that lecithin, owing to its phosphorus, is the active thermogenic agent when oxidized by the adrenoxidase, and that cholesterol is not an antiseptic as its antihemolytic properties have led investigators to believe, but a regulating moderator of thermogenesis in all tissues. The red corpuscles will be shown also to be endocrine glands, the blood platelets representing their secretory product, and to carry on, as messengers kept fed and fit by the adrenals, pulmonary respiration and tissue oxidation.

CONCLUSIONS

1. The diffusion doctrine of physiologists, though studied by them over a century, still fails to explain pulmonary respiration and tissue oxidation despite the paramount importance of these allied functions.

2. As a fundamental function tissue oxidation merges with and influences all other functions; the inability of physiologists to explain it thus compromises and invalidates all fields of medical knowledge, including clinical medicine and therapeutics.

3. The adrenals, as urged by the author for over two decades, afford a foundation for an interpretation of pulmonary and tissue respiration which various branches of medicine, including physiology, have clearly sustained by direct evidence.

4. The admitted inability of physiologists to discover the functions of the adrenals, after seventy-five years' effort, while the experimental evidence they publish sustains the author's interpretation of pulmonary and tissue respiration, afford strong testimony to the effect that this interpretation points at least in the right direction.

5. To disprove the adrenal doctrine the physiologists must explain, individually and collectively, the effects of adrenin recorded in outline in the foregoing pages on all respiratory phenomena, and their striking concomitance; also, and otherwise than by a connection with thermogenesis, the rôle of the cortical lipoids, the phospholipoids in particular.

6. If the physiologists, upon whom clinicians depend for their knowledge of all normal functions, cannot disprove the participation of the adrenals in respiration, the claims of suffering humanity will surely cause them to cooperate, with their colleagues in other fields, in developing the adrenal doctrine.

7. Such a course would bring to light the great value of innumerable data now wrongly considered as sterile or obsolete—including much work by physiologists in endocrinology—and thus supply medicine as a whole a solid foundation such as a sound doctrine of respiration and metabolism would furnish for rapid progress in all directions.

The Clinical Classification of Goitre*

CHARLES GORDON HEYD, M.D.,
New York,
Professor of Surgery, New York Postgraduate Medical School and Hospital

From a considerable experience with postgraduate medical students and a rather ample goitre clinic at the Postgraduate Hospital, it has seemed to the writer that one of the chief difficulties in the diagnosis of thyroid dysfunction by the general practitioner is his inability to classify or to make a nosological entity of an individual presenting symptoms referable to disturbed thyroid function. Recently I had occasion to attend a medical meeting where elaborate statistical charts were presented and saw listed and heard expressed such terms as colloid goitre with basal metabolic rates of 40, 50 and 60. Undoubtedly the essayist on that occasion had a perfectly clear understanding of his own charts and what he was expressing thereby but to the ordinary auditor the two terms colloid goitre and plus basal metabolic rates seemed incompatible.

Goitre or struma means a visible change in the external appearance of the thyroid gland. Clinically it represents an easily determined enlargement of the organ. It is usually employed indiscriminately to connote some change in the secretory activity of the gland. Strictly speaking the term goitre means very little. It is only by an etiological relationship to various clinical syndromes from myxedema to hyperthyroidism that it becomes important and occupies an unusually prominent place in diagnosis.

Disturbances of thyroid function may be viewed from many angles—from the histological, the pathological, the clinical and from the nosological. From the clinical point of view the essential feature will be the presence or absence of the evidence of hyperthyroidism or the presence or absence of the evidence of hypothyroidism. Therefore the first consideration to be made of a particular patient at the time of examination is whether the patient presents the evidence of hyperthyroidism or hypothyroidism. We may say then that we have goitres with hyperthyroidism, goitres with normal secretion and goitres with hypothyroidism.

There are, however, certain types of thyroid dysfunction which cannot readily be placed in such an arbitrary grouping and it has seemed best for our purpose to propose a more extended classification. We realize that there is no clear cut line of demarcation between some of them but for clinical simplicity they may be so separated. It is essentially a clinical division and the value of such grouping is that as soon as the diagnosis is arrived at the treatment of an individual case becomes definitely determined and along well defined lines of therapy. (Chart I.)

The histological unit of the thyroid gland is an acinus lined with cuboidal or low columnar epithelium resting upon a basement membrane and containing colloid material. In the interstitial tissue of the gland are various groups of cells of embryonic origin known as the interstitial cells or embryonic rests of Cohnheim. In the histological sense the thyroid unit may depart in three definite ways; 1, by an hypertrophy of the acinar epithelium, giving a parenchymatous cell type; 2, by an increase or diminution in colloid material, giving a colloid type and, 3, by the development and expansion of new alveoli from embryonic tissue, giving an adenomatous cell type. In the proliferation of the acinar cells or in the changes in the amount of colloid material we have changes occurring in preformed thyroid tissue, whereas in the development of new acini from embryonic tissue we have the creation of an entirely new tissue and one that was not preformed in thyroid substance. These anatomical and physiological states are parallelled by clinical states representing a pure hyperthyroidism from hyperplasia of the acinar cells, a pure hypothyroidism from atrophy or fibrosis of the acinar cells and thirdly, a state of dysthyroidism as the result of the development of adenomatous tissue. The acinar cells are the ultimate secreting units and from these cells is stored the colloid material. Within the colloid material is stored iodine for the elaboration of thyroxin, the colloid material being an accessory material for the production and storage of thyroxin.

It follows then that the purpose of the thyroid is to elaborate thyroxin and to maintain a continuous discharge of it into the circulation (Plummer). Thyroxin is ultimately distributed to the individual cells of the body and is the activator of their biotic chemistry and regulates the rate of internal respiration whereby the balance between the anabolic and catabolic processes of cellular activity are maintained. The elaboration of thyroxin is directly due to the cellular activity of the acinar cells in conjunction with the colloid material working upon a basic iodine substance—iodine constituting forty per cent. of thyroxin.

The more active the epithelial hyperplasia the less colloid material and iodine are stored in the thyroid as the amount of iodine content varies with the amount of colloid material present.

There is less iodine in the gland of hyperthyroidism than in the normal gland but Reid Hunt has shown that there is more iodine in the blood as it is more slowly excreted from the system contrary to its usual rapid elimination. Marine has shown that colloid goitre contains more iodine in the whole gland than the normal thyroid but weight for weight colloid goitre contains less iodine than the normal thyroid, so that although in the colloid goitre there is more iodine, this is due to its enlarged bulk and not that the individual acini contain more iodine.

It is interesting to digress and to consider the two essential ways in which thyroid secretion may be changed. On the one hand we have acinar cells which are the direct secreting individuals of each secretory unit and we have interstitial cells or fetal

*Clinical Lecture delivered at the New York Postgraduate Medical School and Hospital, October 19, 1923.

cells of Cohnheim, which are scattered more or less throughout the gland. It is an accepted fact that the degree of thyroid secretion directly parallels the activity and hyperplasia of the acinar cells. Accordingly, there is direct relationship between the amount and degree of secretion and the amount and degree of hyperplasia. Wilson, a number of years ago, was able to write the clinical picture of a case of Graves's disease from an examination of the histological sections. The acinar cells increase in number by three well defined methods: 1, by individual proliferation of the cells leading to an increased number of cells in the acinus with loss of colloid material; 2, by infolding or invagination and papillomatous hyperplasia of the acinar cells and; 3, by budding with the formation of independent acini. The more increase there is in acinar cells the less colloid material so that again there is a certain parallelism between the hyperplasia and the amount of colloid material present. If the interstitial cells proliferate they produce individual discrete tumors, socalled adenoma, which have their own specific secretory activity. By proliferation of the interstitial cells a single or multiple adenoma may be produced and the degree of formation of adenomata may bring about atrophy and destruction of normal thyroid tissue until practically the entire thyroid is replaced with tumor formation and such thyroid tissue as may be present will exist in the posterior capsule or at the poles. A less frequent condition has been referred to by Goetsch which he defines as diffuse adenomatosis, where there is a proliferation of the interstitial cells more or less throughout the thyroid producing practically an adenomatous replacement of the thyroid tissue.

It is interesting to look at goitre from another angle. The thyroid is essentially the regulator of metabolism, defining metabolism as the sum total of all changes that occur in the human body. This would suppose that the thyroid acts as an independent regulating mechanism. A further consideration shows, however, that among the endocrines there is a duality of function and if one group loses its function it exerts an influence upon the others. Hence any disturbance of the thyroid must also take into consideration whether the symptom complex exhibited is a monoglandular affair pertaining only to the thyroid or whether it is a pluriglandular affection in which other symptom groups are introduced representing the disturbance of other glands than the thyroid. For example, Murphy in his clinics a number of years ago repeatedly alluded to the fact that an undescended testicle was often accelerated in its descent by the giving of thyroid extract, particularly if given previous to the eighth year. The reaction of the patient with hyperthyroidism when adrenalin is injected is the basis of the Goetsch test and points to the fact that the entire sympathetic system is hypersensitive in the presence of increased thyroid secretion. One is warranted in believing that every tissue in the body is in a state of oversensitization under the continuous influence of hyperthyroidism. The presence of glycosuria in hyperthyroidism is not a mere casual observation but is a very definite and sequential symptom as the result of disturbance in thyroid function.

When we consider hyperthyroidism we should determine whether there is a pathological or physiological change in the thyroid gland. An exaggeration of normal function may exist from a variety of influences and this hyperfunction might exhibit itself in variations in the quantity of secretion or in its quality and hyperthyroidism might exist as the result of an increased functional capacity of the gland without intrinsic pathological change. On the other hand, we may have a pathological gland but with a thyroid secretion that is normal or in excess or diminished.

The measuring of the sum total of metabolic changes in the body under the socalled basal metabolic test has enabled us to determine accurately the degree of hyperthyroidism. It is to be remembered, however, that the basal metabolism is higher than normal in youth, in fever, in lymphatic leucemia and in pernicious anemia, occasionally in cardiac disease and more rarely in severe cases of diabetes. It is also lower than normal in old age and wasting diseases, and inanition is capable of depressing the basal metabolic rate for a long continued period of time. There are in addition to the thyroid gland three other glands that are supposed to have an influence on metabolism. Of primary importance is the suprarenal gland and less so the gonads and the pituitary gland. The gonads apparently achieve their influence upon metabolism through their association with the thyroid rather than directly, for the lowered metabolism following castration is apparently due to a depression of thyroid secretion rather than directly to the gonads.

CHART I

Clinical Classification of Goitre

GOITRES WITH HYPERTHYROIDISM.

1. Goitre of adolescence.
   Physiological gland with overfunction.
2. Goitre of Graves's disease.
   Pathological gland with overfunction and dysfunction.
3. Goitre of adenoma—adenomatosis.
   Pathological gland with overfunction.

GOITRES WITH HYPERTHYROIDISM OR NORMAL THYROXIN SECRETION.

1. Simple, endemic goitre and colloid goitre.
   Pathological gland—secretory activity normal or diminished.
2. Goitre of adenoma.
   Pathological gland—secretory activity normal or diminished.

Let us now consider the clinical groups that I have alluded to and see if we can establish their individual characteristics (Chart I). Two of my associates—Selinger and Moolten—have recently made a study of the goitre of adolescence and have published their conclusions. I am availing myself of quoting liberally from their papers. This particular type of goitre, sometimes called physiological hypertrophy and hyperplasia or the goitre of puberty, is associated with a mild or slight hypertrophy and hyperplasia of the acinar cells. As a rule there is a varying degree of hyperplasia of the acinar cells with infolding; rarely papillomatous proliferation. The colloid material may be apparently normal in amount or slightly diminished depending upon the degree of hyperplasia. This type of goitre is peculiar in that it manifests itself during adolescence. If one desires to study the goitre of adolescence on a large scale he has only to stand at any of the cross-

town streets between Fourteenth and Forty-second Streets at eight o'clock on any morning of the year and see the army of adolescent young women going forth to work, many of them showing slight thyroidal enlargement and many of them exhibiting the clinical syndrome and symptomatology of slight hyperthyroidism.

In April 1917 Marine (1) made a survey of goitre among the school children of Akron. 3872 girls were examined, with the following results:

Normal thyroids	1688	43.6 per cent.
Slightly enlarged thyroids	1931	49.9 per cent.
Moderately enlarged thyroids	246	6.3 per cent.
Markedly enlarged thyroids	7	0.2 per cent.
Among these there were adenomas	39	1.0 per cent.

If a group of these persons were taken and arranged from left to right in regard to the severity of their symptoms we would have at the left hand extremity those nearly akin to the normal and at the right hand end those that showed marked hyperthyroidism and were potentially a Graves's disease. Most of these cases undergo a spontaneous cure, as soon as the physiological demand for increased thyroid secretion for trophic purposes has ceased.

Moolten writes that the consensus of scientific opinion in this country tends to regard this type of goitre as a deficiency disease. Plummer, Kendall, Rogers and Marine and others have irrefutably shown that iodine is essential to normal thyroid activity: that subiodism produces structural as well as functional changes in the thyroid gland: and that the physiological action produced by thyroid extract is always proportional to the iodine content. In the light of this knowledge one is constrained to accept the view that adolescent goitre is due to a relative lack of iodine.

They all exhibit plus values in their basal metabolism and the essential element in their thyroid instability is a variation in the iodine metabolism of the gland. Various bodily factors tend to produce a definite, subnormal species of humanity, in whom there is an insufficient amount of thyroid extract thrown into the circulation to carry on a normal metabolism. In consequence, the only source of thyroid extract—the thyroid gland—"is tapped" and in response to the call the gland becomes overactive and hyperplastic. There is a peculiar physical stature to these patients. They are not of robust type, their heredity is usually defective in that they were not born with strong stable organisms. They are thin, emotionally unstable, possessing bad judgment in regard to their diet and personal hygiene. Defective nasopharyngeal apparatus is present in addition to bad teeth and other stigmata of incomplete biological development.

In the hyperthyroidism of socalled adolescent goitre there is a frequent association of pulmonary tuberculosis. We have had occasion to make a critical study of a number of cases of incipient tuberculosis in undernourished young women and have found that the majority have a slight enlargement of the thyroid with minor degrees of increased basal metabolism. In considering an increased pulse rate in young women with a clinical picture that would ordinarily suggest a mild transitory hyperthyroidism it is well to canvass thoroughly the possibility of a low grade tuberculous intoxication from an incipient phthisis. Another interesting fact is that many of the juvenile patients with slight external protuberance of the thyroid, with some tachycardia, minus or plus values in basal metabolism and with a pulmonary tuberculosis have a hypoplastic vascular system, particularly a small sized heart.

Simple goitre may be defined as one with an enlarged thyroid and no hyperthyroidism, while Graves's disease is a goitre exhibiting hyperthyroidism with exophthalmos.

The immediate cause of simple goitre is lack of iodine. Marine states that thyroid hyperplasia in this group of cases is a compensatory reaction arising in the course of a metabolic disturbance and immediately depending on a relative or absolute deficiency of iodine. If the available supply of iodine is moderately decreased there is compensatory hyperplasia initiated in the thyroid structures and hence endemic or simple goitre is essentially due to a deficiency of iodine.

The thyroid in simple endemic or colloid goitre is usually symmetrically enlarged and smooth although either lobe may be enlarged over the other or the enlargement may be located in the isthmus. On microscopic examination the acini are swollen, the acini cells are thin, flat, deeply staining, the colloid material and nonabsorbable secretions are increased and the whole picture is that of a gland producing a lessened unit of secretion. It is necessary to consider the whole gland and not a circumscribed portion. Halsted by excising portions of the thyroid induced compensatory hypertrophy in other portions of the gland and occasionally in a section from a simple or endemic goitre new acini may be seen, occasionally infolding and reduplication, rarely papillary production. This goitre occurs preeminently in the Alps, and the Himalaya regions. The most important areas in our country are the Great Lake Basin, the Cascade Mountain regions of Oregon, Washington and British Columbia. The researches of McCarrison of India have emphasized the importance of gastrointestinal infection as a goitre producing influence and stresses that the factors that give rise to goitre districts hinge around the supply of iodine and the needs of the thyroid gland for iodine, irrespective of the anaerobic pathogenicity of the intestinal tract.

Two separate and distinct pathological conditions of the thyroid gland exhibit hyperthyroidism in its most acute form, namely, the goitre of Graves's disease and the adenomatous goitre with hyperthyroidism.

The isolation in 1914 by Kendall of the active principle of thyroxin from hyperplastic thyroids gave a marked impetus to the study of the physiological action of thyroxin on the body. In 1915 Plummer formulated certain deductions as to thyroxin. In substance he stated that thyroxin acted directly or indirectly on all cells throughout the body. It is the agent that accelerates the formation of potential energy and which is available on excitation of the cells and that "hyperthyroidism is the physiological status of an individual otherwise normal when the thyroxin maintains basal metabolism above the normal." Furthermore, that all the phenomena which usually go with hyperthyroidism are always associated with an elevation of basal metabolism.

It would seem then that hyperthyroidism represents a dual condition, one in which the etiological factor is the adenomatous goitre and the other one the goitre of Graves's disease. Crotti does not believe in the duality of hyperthyroidism or in the separation of the adenomatous hyperfunctionating type of goitre from the hyperthyroidism of exophthalmic goitre.

It is interesting to note that the taking of thyroid extract or the injection of thyroxin will produce in exact similarity every symptom of the hyperthyroidism of adenoma, whereas it is impossible to produce in similitude the symptoms of hyperthyroidism of Graves's disease either from thyroid feeding or from the injection of thyroxin. This would seem to lead to the conclusion that the hyperthyroidism as exhibited in Graves's disease is in a qualitative manner different from the hypersecretion as evidenced in the adenomatous goitre.

The studies of Plummer on the effect of giving Lugol's solution for the hyperthyroidism of Graves's disease would seem to confirm the impression that the hyperthyroidism of Graves's disease is due to an incomplete or preformed molecule of thyrotoxin, for under the administration of Lugol's solution the clinical picture of hyperthyroidism of Graves's disease changes to the clinical picture that more nearly simulates that found in the hyperthyroidism of adenomata. Correspondingly there is a marked drop in the basal metabolic readings within two or three days after the administration of Lugol's solution. These observations of Plummer would seem to offer additional proof that in the hyperthyroidism of Graves's disease we have a picture that is essentially different from the hyperthyroidism of adenomata and that the mechanism of the intoxication is also different.

In adenoma there is a tumor growing in the thyroid substance. Accordingly we have a pathological gland with or without hyperthyroidism. In regard to the hyperthyroidism of adenomatous goitre there are two ideas present, one that the adenomatous cells elaborate and deliver an excess of thyroxin; the second idea is that the adenoma in some peculiar way stimulates the surrounding thyroid tissue to hyperfunction. The evidence would seem to support the idea that it is the adenomatous cells themselves which hyperfunctionate. There can be no doubt that the adenomatous tissue by and of itself can elaborate thyroxin and store up colloid and iodine.

The embryonal cells of the adenomatous goitre are stimulated into growth by a variety of unknown factors and for a long period of time the newly created adenomatous tissue cannot properly function. It can, however, store colloid and iodine long before it is in a position to elaborate thyroxin. The essential differences in the clinical manifestations of the adenomatous goitre and the exophthalmic goitre are, first, that the adenomatous goitre is first noted as a thyroidal enlargement from five to ten years earlier in life than the exophthalmic; secondly, the average duration of symptoms in the exophthalmic goitre is nine months, whereas in adenoma it is seventeen and a half years; thirdly, exophthalmos occurs within three months after the appearance of hyperthyroidism in an average of fifty per cent. of cases of exophthalmic goitre and within two years in eighty-seven per cent. of cases of exophthalmic goitre and is only present in about three per cent. of toxic adenoma (2); fourthly, the average interval between the time the adenomatous goitre was first noted and the onset of symptoms of hyperthyroidism is seventeen and a half years (Plummer). The hyperthyroidism of adenoma is characterized by an insidiousness, by an erratic course over a long period of years, of low intensity; finally, after a period of an average of seventeen years the adenomatous goitre is frankly expressed in conditions of clinical hyperthyroidism.

The characteristic and outstanding feature of hyperthyroidism of Graves's disease is the fact that its complete elaboration takes place within a relatively short space of time and it is the rule that when the case is first seen the clinical picture is usually complete and the outstanding features of the disease are already present.

The very definiteness of the clinical course in hyperthyroidism due to Graves's disease is one of its consistent and outstanding features. This course may theoretically be divided, however, into four stages: 1, the stage of development in which the basal metabolic rate is usually higher than the symptoms would seem to indicate; 2, the stage of increasing intensity in which the basal metabolism parallels the symptomatology; 3, a period of retrogression in which the basal metabolic rate falls to the normal more rapidly than do the symptoms; and finally, 4, the stage of remission in which the basal metabolic rate is somewhere near the normal base line although the symptoms of hyperthyroidism may persist as the result of chronic degenerative changes in the cardiovascular apparatus, in the sympathetic system, in the autonomic muscular system, etc. (Else).

In the hyperthyroidism of adenoma surgical procedure is directed to removal of the tumor. In the hyperthyroidism of exophthalmic goitre, however, the procedure is planned to diminish the actual amount of thyroid tissue by the removal of varying amounts of diffuse hypertrophied, hyperplastic tissue. Ligation in adenoma is of no value. Ligation in exophthalmic goitre is one of the procedures to diminish thyroid activity. Removal of the adenoma is sufficient to cure that type of hyperthyroidism whereas on the other hand the hyperthyroidism of Graves's disease requires the resection of the greater portion of both lobes and isthmus to reduce the activity of the thyroid within normal limits.

Finally, there is a group of patients who have suffered continuously for many years from hyperthyroidism. They represent what Crotti calls a "burnt out thyroid." Landstrom, quoted by Ochsner, has shown that in all cases in which hyperthyroidism resulted in an actual dilatation of the heart the organ never returned to normal even after thyroidectomy had brought the pulse back to a fairly normal rate. These patients have an irreparable damage to their nonstriated muscle fibres, they have the brown degeneration of the cardiac muscles with varying degrees of myocarditis. They have various types and stages of nephritis: their cerebral tissues are physiologically unstable and they are essentially chronic invalids irrespective of what is done for

them either medically or surgically. They are incurable, so far as the permanent degenerative lesions that the hyperthyroidism has produced, are concerned. We have seen a number of patients who exhibited hyperthyroidism for ten or fifteen years and when they came to us their thyroid condition was quite secondary to the degenerative processes that are exhibited in all the higher forms of body tissue.

The Real Value of the Basal Metabolic Rate

With an Analysis of 470 Case Reports

ARNOLD S. JACKSON, M.D.
Madison, Wisconsin.

Because of unfortunate early experience with the basal metabolic unit many physicians were prejudiced against its use and blindly refused to recognize its value. The reasons for their attitude are legion. The two outstanding causes for the antagonism which the metabolic machine gained for itself are now quite apparently traceable to no fault on the part of the machine but to incompetence on the part of the technician and inadequate knowledge of the significance of the basal metabolic rate in relation to diseases of the thyroid on the part of the physician.

The inability of many physicians to interpret the basal metabolic rates in the light of the clinical findings and the grave errors they made in differential diagnosis resulted in the natural animosity of certain leaders of the profession. They looked askance at patients with colloid goitres who had been advised to submit to operation because an inaccurate test showed a rate of plus twenty-five. They had reason to become alarmed on listening to the queries of men who wondered why a patient with a rate of plus fifty had not done well following operation. C. H. Mayo has again and again emphasized that regardless of the basal metabolic rate, a patient who is on the verge of a crisis may be operated on only with the gravest risk. A basal metabolic rate of plus fifty in a patient about to go into a crisis gives much more cause for concern than one who has a rate of plus seventy but has passed through a crisis and is improving clinically.

In 1920 a Tissot unit was installed in this clinic with the kind assistance of Boothby and Sandiford of the Mayo clinic. The 470 patients who have since been referred to this department for basal metabolic rate readings form the basis for the analysis presented in this paper.

THE BASAL METABOLIC RATE IN EXOPHTHALMIC GOITRE

Differential diagnosis.—The basal metabolic rate is of inestimable value in the differential diagnosis of mild, incipient cases of exophthalmic goitre from those of cardiac neurosis, chronic nervous exhaustion, neurasthenia, and the nervous phenomena accompanying the menopause. While the majority of cases may easily be recognized by the clinical signs and history, some offer most difficult diagnostic problems even to specialists in the study of thyroid diseases. For example, in girls a symmetrical enlargement of the gland seen at puberty is accompanied by nervous symptoms, tachycardia and palpitation, and in a small percentage of these cases, the socalled vascular type, thrills and bruits are present. A normal metabolic rate assures the clinician that he is dealing with a vascular colloid goitre. To be assured beyond doubt that a patient does not have hyperthyroidism is a source of gratification to the patient as well as the physician.

TABLE I

STUDY OF THE BASAL METABOLIC RATE IN 470 PATIENTS.

	Number of Patients	Average Basal Metabolic Rate
Exophthalmic goitre	56	+54
Adenoma with hyperthyroidism	60	+38
Adenoma without hyperthyroidism	78	+ 6
Colloid goitre	47	+ 2
Malignant thyroid	3	+12
Myxedema	2	—24
Hypothyroidism	15	—15
Obesity	12	— 2
Neurasthenia	12	+ 8
Chronic nervous exhaustion	24	+ 7
Normal	31	+ 5
Cardiac neurosis	30	+10
Hypopituitarism	10	—11
Pellagra	1	+ 9
Addison's disease	2	— 6
Pernicious anemia	7	+ 2
Diabetes	12	— 6
Pregnancy	8	+ 8
Miscellaneous	60	+ 5

TABLE II.

THE BASAL METABOLIC RATE IN EXOPHTHALMIC GOITRE

Average preoperative rate	+54
Maximum rate	+92
Minimum rate	+25
Rate after one ligation	+39
Rate after two ligations	+33
Rate after thyroidectomy	+ 6

Index of hyperthyroidism.—While the rate may follow the progress of the disease in general and register the degree of thyroid activity, it is not an index of the patient's ability to withstand operation. For example, although one patient in this series of cases had a basal metabolic rate of only plus forty-four, he was considered a far greater risk for operation than another whose rate was plus ninety-two. The risk in the first case was greater because hyperthyroidism had existed for only three months; there had been recent rapid loss in weight and strength; the patient was beginning to suffer from gastrointestinal disturbances and was on the verge of a crisis. Even a hot water injection was attempted with risk. On the other hand, the patient with a basal metabolic rate of plus ninety-two had passed through a crisis and enjoyed a period of

Fig. 1

Fig. 2

Fig. 3

Fig. 1.—Patient with myxedema following operation for recurrent exophthalmic goitre in 1922. Six months later severe ostemyelitis developed with multiple bone involvement and subsequent thyroiditis of the remainder of the gland. The basal metabolic rate was minus twenty-six per cent.; following treatment with thyroxin the rate rose to normal with great clinical improvement.

Fig. 2.—Same patient as in Fig. 1. Two months following operation the basal metabolic rate was plus five per cent. and the patient had gained thirty pounds.

Fig. 3.—Patient with exophthalmic goitre and a basal metabolic rate of plus sixty-four per cent. Ligations and thyroidectomy were performed under local anesthesia with an uneventful recovery.

comparative remission of symptoms. Ligation was performed with only a mild reaction. In the majority of patients with only slight loss in weight and strength, ligations are seldom indicated when the basal metabolic rate is below plus fifty, while primary thyroidectomy should seldom be performed in the presence of a rate higher than this.

Indication of the result of treatment.—During the past year wonderful progress has been made in the preoperative handling of these cases with Lugol's solution of iodine. It has been possible to decrease preoperatively the metabolic rate an average of twenty points in a series of thirty cases. This reduction in the rate is accompanied by a proportionate clinical improvement, the patients become more quiet and composed, and no longer thrash about the bed and chafe their extremities. The necessity for ligation is obviated in many cases. It will be noted in Table II that the basal metabolic rate dropped an average of fifteen points after one ligation and twenty-one points after two ligations.

Finally, it is a source of gratification to observe the steady downward slant of the metabolic curve after the different operative procedures until three weeks after thyroidectomy when the majority of rates have returned to normal. Occasionally, a few months after operation the patient makes some complaint and it is useful to know whether the thyroid is still overactive. A normal rate eliminates the possibility that the surgeon has failed to remove sufficient gland and indicates that the patient has simply overestimated his recuperative abilities or that some foci of infection, such as teeth and tonsils, have been overlooked. All my patients are required to report to me at frequent intervals for observation and advice; all foci are eliminated, and special attention is paid to refraction of the eyes.

Fig. 4

Fig. 5

Fig. 4.—Exophthalmic goitre in a boy aged nineteen years. On admission the basal metabolic rate was plus forty-four per cent., and he was rapidly losing weight.

Fig. 5.—Same patient as in Fig. 4, two months following double ligation and a three stage thyroidectomy. He gained twenty-six pounds and the basal metabolic rate is now plus eight per cent.

ADENOMA WITH HYPERTHYROIDISM

The average adenoma does not present symptoms of hyperthyroidism until the patient is forty-four years of age. Many cases of hyperthyroidism are induced in simple adenomas in young persons through the promiscuous use of iodine. Kocher, one of the first to recognize this

condition, called it *Jod Basedow,* and repeatedly warned against it. In such cases of induced hyperthyroidism it is well to determine the extent of the damage and also to make metabolic tests at frequent intervals to ascertain the progress of the hyperthyroidism. In twenty-five per cent. of the patients with toxic adenoma whom I observed during the past year a toxic condition had developed as a result of the administration of iodine. In the majority of instances iodine had been given in such quantities and over such long periods of time that thyroidectomy was necessitated. In a few cases the patients gradually recovered through nonoperative measures.

The attention of the propaganda department of the American Medical Association was called to a certain quack remedy, sixteen bottles of which would cure any goitre. This remedy, which has induced hyperthyroidism in hundreds of patients in the middle and far West, was analyzed and found to contain potassium iodide. The remedy was exposed in the *Journal of the American Medical Association* but it has not been entirely suppressed and is still taking a heavy toll from its victims.

COLLOID GOITRE

In colloid goitre the basal metabolic rate is chiefly of value in following the course of medical treatment with iodine, thyroid extract, or thyroxin, and determining the patient's tolerance for these substances. Certain patients will tolerate thyroid extract better than iodine and will show much greater improvement with one than the other. At present I am treating nearly four hundred children between the ages of ten and twenty with the various preparations. The majority are receiving iodine in the form of iodostarine, after the method advocated by Marine and Kimball. Certain of these cases are selected for controls and the basal metabolic rates are frequently determined. By pushing medication in many of these children and yet keeping the rate between plus five and plus fifteen, it has been possible either to reduce many of the colloid enlargements to a very great extent or cause them to disappear altogether.

MYXEDEMA AND HYPOTHYROIDISM

The metabolic rate is of great value in cases of hypothyroidism, first of all in determining or confirming the diagnosis, and second as an indication of treatment. The diagnosis in these cases is frequently overlooked by the best of clinicians and treatment for chronic nephritis or anemia is continued for long periods without result. A basal metabolic rate of minus fifteen or more at once settles a suspected diagnosis.

The aim of the treatment is accomplished by bringing the metabolic rate to normal through the intravenous use of thyroxin, or by the administration of thyroid extract by mouth. The rate may then be maintained within normal limits by the correct daily dose.

DISEASES OTHER THAN THOSE OF THE THYROID GLAND

In conditions or diseases other than those of the thyroid gland the basal metabolic rate has not as yet proved to be of consistent aid either in diagnosis or treatment. The rates reported in cases of tuberculosis of the thyroid gland have been consistently high. In malignancy of the thyroid our own rates as well as others reported have been variable. A variable rate is also the rule in diseases of the other internal glands of secretion as well as in diseases such as pernicious anemia, pellagra, epilepsy, diabetes, arthritis and Hodgkin's disease.

SUMMARY

The basal metabolic rate, when accurately determined, is of great value in the diagnosis and treatment of the various diseases of the thyroid gland. The rate is not an index of the patient's ability to withstand operation, but it is a valuable aid when interpreted in the light of the clinical factors. The greatest value of the metabolic rate in diseases other than those of the thyroid lies in eliminating the possibility of overactivity on the part of the gland.

Sidelights on Diabetes

JOHN AULDE, M.D.,
Philadelphia.

While much valuable data, both scientific and clinical, have been accumulated within the past two years, it must be evident to the critical student that the end is not yet, that there are still important factors to be considered which should go along with the present information regarding the treatment of diabetes. This statement is warranted by the following memoranda (1) extracted from the report of the Insulin Committee of the University of Toronto, as follows: "In diabetes there is a decreased production of insulin, due to the weakened function of the islands of Langerhans. . . . The etiological factor or factors causing this damage to the pancreas have not been discovered. It is known, however, that diets containing excessive quantities of carbohydrates, or proteins, fats and carbohydrates in improper proportions or quantities, as well as infections, further weaken the function of the already damaged pancreas." It is stated "The artificial administration of insulin restores to the body a normal metabolism of carbohydrates, fats and proteins," but, "Although the administration of insulin is capable of relieving cardinal symptoms and signs of diabetes mellitus, *one must not conclude that insulin can replace the dietetic treatment of the disease.*" Still another quotation should be added, because the item will prove of vast importance to present as well as to future investigators—"In some cases the pancreas has so regained its power to produce insulin that the daily dose need not be increased."

The significance of the foregoing items will be apparent when the claim is put forward that as a result of a deficiency in the diet, the function of the delicate structures of the pancreas has been arrested or destroyed—but how? The correct answer to this important question must be determined by means of chemistry and electricity. This assertion is warranted by the data which appear in an article (2) by Francis C. Grant, of Philadelphia, which gives in detail an account of the use of an electrical apparatus by which "the presence of a subcortical growth was determined by passing the needle into the brain substance and noting the sudden drop in resistance when the tumor was encountered." In describing the operation he says: "At the operating table we have used the apparatus in twelve cases. Of these, five were gliomas. In every case, the resistance of the tumor was only half that of the normal brain. . . . Experiments with a view to determine the electrical resistance of the normal brain and different areas of the same brain were made in a series of ten dogs, the resistance in all of them being approximately the same. In a series of forty formaldehyde hardened brains containing proved gliomatus tumors, the gliomatous tissue consistently produced a resistance from a half to two thirds less than that of the adjacent normal tissue. Formaldehyde hardened tissue gives a much higher resistance than living brain tissues, and the resistance of the preserved normal tissues varies from specimen to specimen; but in every instance the gliomatous tissue is strikingly less resistant to the current."

Now, my impression is that the effect on the pancreatic function is due to magnesium infiltration affecting the islets of Langerhans and as magnesium is a poor conductor of electricity, it naturally follows that a diabetic pancreas examined with this apparatus would show greater resistance than normal. And if this deduction is found correct by the electrical test, it would be a simple matter for the physiological chemist to determine whether or not the diseased pancreas contained a surplus of magnesium as compared with the normal pancreas. It seems to me that these tests would be far more satisfactory and more conducive to progress in medical science than the assumption of Allen that diabetes is due to "functional overstrain."

This suggestion has already been proved, from a clinical point of view, rather indirectly it is true, but it goes to confirm the latest information regarding the function of the parathyroids in the metabolism of calcium. Forrest (3) of Newcastle-on-Tyne reports a series of five clinical cases in which parathyroid extract was given by mouth, in conjunction with insulin, and the blood sugar curve compared with that following the administration of insulin alone. By means of this combination medication there was a marked reduction and Forrest concludes, "From the cases mentioned above it is evident that parathyroid extract exerts definite action on the blood sugar curve after exhibition of insulin. Whether this will be of any importance as regards treatment is not yet clear. Parathyroid alone does not appear to have any action on the blood sugar; such changes as have been noticed could be explained as the result of starvation. Investigations are in progress to ascertain the therapeutic value of the combination."

In this connection it should be recalled that parathyroid is supposed to exert a distinct and demonstrable action in the treatment of socalled uremic poisoning, a fact to which I called attention in a previous article (4). Rogers (5), a British Medical Officer, India Service, published a clinical record of one thousand cases of uremic poisoning in the algid state of cholera. Upon adding four grains of calcium chloride to the pint of physiological salt solution for transfusion, the mortality was reduced seventy per cent. By way of explanation I added the following: "There are two types of uremic poisoning, one with profound depression, in which the output of ammonia is largely increased, but there are no convulsions; in the other the excretion of ammonia is retarded, convulsions being the dominant feature. In all cases, however, the calcium content of the blood is deficient. . . . "Laboratory investigations come to our aid by demonstrating that an enzyme produced by the thyroid gland is responsible for converting ammonia from the systemic nitrogen, that another enzyme from the suprarenal cortex acts upon ammonia, changing it into a poisonous substance, and finally, a parathyroid ferment (hormone?) converts this toxic principle into the harmless urea. That is to say, the poison of uremia is an intermediate product between ammonia and urea and results from glandular deficiency."

By way of explanation may I be permitted to quote further (*loc cit.*). "Both calcium and magnesium are proximate principles and possess several important properties in common—they are antacid, catalytic and reconstructive. Whatever may be the chemical status in the course of distribution, we note that ultimately they become colloidal and that this is their intracellular condition. As colloids they acquire increased surface energy and enact the rôle of ferments—mineral ferments, but here the analogy ceases. . . . When the central nervous system or any part of its mechanism, the muscles, the bone structure or the glandular appendages, including the ductless glands, are robbed of their essential chemical constituents, their normal function is arrested or destroyed. . . ."

Another interesting item connected with the study of diabetes mellitus should not be overlooked—I refer to the possibiliity, or rather, the probability that other tissues besides the pancreas may be involved. For example, an eight line paragraph appeared recently (5) referring to the publication (6) of W. L. Brown: "While the discovery of insulin completely proves that the cell islets of the pancreas form an internal secretion which promotes the assimilation of sugar, it does not prove that all diabetes is due to a pancreatic lesion. The fact that pituitary extract can antagonize insulin provides new support for the view that diabetes may be due to a more profound and subtle disturbance of metabolism than a lesion of one gland." More direct is the announcement of Richards of the University of Pennsylvania. In the course of a lecture or informal talk at a recent meeting of the Philadelphia County Medical Society, he was giving a detailed account of his experiments upon depancreatized dogs, with a view to determine, if possible, the special function of the tubules as well as the glomeruli in the output of sugar. Incidentally, he stated that an examination of the urine as it was

discharged from the pelvis of the kidney showed a considerable amount of sugar, but when it reached the bladder the sugar had disappeared, showing that it is the function of the ureteral membrane to take up sugar (imbibition), and my impression is that many cases of socalled diabetes which respond so readily to calcium medication are cases of this special character. The ureteral membrane has become charged with magnesium in excess, owing to the constant action of the acid urine, which eliminates the calcium, so that this tissue shows that magnesium interferes with the permeability of the organized structures. In other words, the normal nucleoproteins are transformed by the presence of soluble magnesium salts into magnesium nucleoproteins, which lack the property of imbibition—and this accounts for the improvement in mild cases of diabetes from dietetic treatment alone, as well as for the decidedly beneficial effects of parathyroid medication in conjunction with insulin.

Physiological and Anatomical Considerations of the Ductless Glands*

HYMAN GOLDSTEIN, M.D.,
New York

One should have a comprehensive knowledge of the physiology of the ductless glands and its anatomical basis, in order to understand the great number of clinical syndromes that present themselves from various endocrine disorders, and be able to interpret them. Pluriglandular disorders predominate, but symptoms of one gland may make up the whole background of the illness. Thus you may be dealing with a uniglandular type, i. e., thyroid, pituitary, adrenal, thymus, pineal, gonadal and others, with such symptoms predominating associated with compensatory hyperfunction or hypofunction of other ductless glands. Every clinical case needs individual study.

THYROID GLAND

It is a ductless compound alveolar gland, extremely vascular and situated at the front and sides of the neck extending upwards upon each side of the pharynx. It is relatively larger in children and females, and consists of two lobes and an isthmus, occasionally we find a middle lobe. We frequently find accessory thyroids with the x ray. At birth most of the alveoli are empty, but soon become more or less filled with colloid substance. There are two sets of cells; secreting cells and resting or reserve cells (nonsecreting). Gley showed that while removal of the thyroid alone does not necessarily cause death, it was the removal of the parathyroids which caused the nervous phenomena and the fatal ending. That the organ is a secreting one is known by the fact that it can be transplanted to other parts of the body. There are convincing data indicating an intimate relationship between thyroid and parathyroid, anatomically, physiologically and pathologically. There is also an important connection between the thyroid and adrenals, the former and mineral, protein and fat metabolism. It increases nitrogen excretion and other tissue wastes.

The thyroid parathyroid secretions therapeutically increase the sensitiveness of the phosphorus of all cells, especially the nuclei, to the oxidizing action and enhance not only nutritive and metabolic processes but augment the autoprotective and immunizing power of the blood, greatly increasing the opsonic index. It also stimulates the hemopoietic organs. The great influence of the thyroid gland on oxidation enhances all vital processes and mental and physical development. Intelligence and the cerebrospinal system are partially influenced owing to its wealth of phosphorus. All organs being the seat of increased metabolic activity and nutrition, the intestinal, renal, cardiac, cutaneous and hepatic functions are all enhanced. Even the hair grows bountifully when thyroid is given when the defect is due to impaired thyroid nutrition. It counteracts premature senility and keeps up the tone of the muscles. The phenomena evoked by the pituitary body and the thyroid show considerable parallelism. Nucleoproteid is found in the thyroid. Dr. Kendall isolated a crystalline substance called thyroxin from the thyroid which contains sixty per cent. iodine.

PARATHYROID GLANDS

These are small ductless glands usually four in number, the size of orange seeds, that lie upon the posterior surface of the lateral lobes of the thyroid. They are constant in man and more distinct in infants than in adults. The cells are of two types: 1, resting or clear cells which are numerous; and 2, granular or oxyphilic cells, that are larger, granular and take strong eosin stain. Some lobules have a distinctively alveolar structure and contain colloid in its lumen.

The parathyroid secretion serves to neutralize the toxic wastes which give rise to tetany. It also plays an important part in calcium metabolism. It is considered that tetany is an intoxication from guanidine compounds which is destroyed by parathyroid secretion and also made inert when precipitated by the calcium. With thyroid it increases tissue resistance, increases the number of leucocytes and the opsonic index. It influences bone growth, dentition and general nutrition. Dr. Vines uses parathyroid with

*This article is a summary. The full text will appear in the reprints.

success in varicose veins, due to improved calcium metabolism.

PITUITARY BODY

The pituitary gland is a pinkish gray vascular mass thoroughly protected by nature, centrally located on the base of the skull, surrounded by the sella turcica bony encasement within the diaphragma sella which is pierced by the infundibulum. It consists of the anterior or glandular portion which is larger, and, the posterior or nervous part. There is also a pars intermedia and Dr. Tilney described the pars tuberalis, both of which seem to be a part of the anterior lobe, but structurally are different. The secretion derived from the posterior lobe is considered by many to find its source in the pars media. It causes a marked rise of blood pressure; increased flow of urine due to increased kidney concentration; increases the secretion of milk; heart rate slowed and blood pressure raised; mineral metabolism and calcium excretion are influenced; all involuntary muscle especially the uterus is stimulated and its tonicity improved by direct action upon the muscles, and, carbohydrate metabolism is influenced by accelerating glycogenolysis in the liver. It also influences general metabolism and improves appetite. It is also said to increase the quantity of cerebrospinal fluid.

Anterior lobe secretion stimulates bone growth and connective tissue generally. With thymus and adrenal cortex it has a regulating influence upon the normal development of the reproductive glands. Feit has shown the close relationship of syphilis to hypophyseal involvement. It also influences calcium retention and mineral metabolism. Through the fat tissue utilization power it exerts, it spares protein. By virtue of this it is useful in skin conditions as scleroderma, seborrhea, acne, gouty concretions and persistent urticaria. Because of its part in calcium metabolism it has a favorable influence on dentition, prevents decay, favors orthodontia growth or correct occlusion. It also stimulates sympathetic and mental impulses. Pituitary extract diminishes the pulmonary blood pressure and, together with adrenalin which relaxes the bronchial musculature, has a favorable influence in bronchial asthma.

Burnier in 1912, described a type of cases showing optic atrophy, adiposity, atrophy of the external and internal genitals and dwarfism. It is a combination of posterior and to a smaller extent anterior pituitary insufficiency. Froehlich described cases of posterior pituitary insufficiency and thyroid insufficiency. Cushing described cases showing hyperpituitary secretion at one time and hyposecretion at another and also cases showing hypersecretion of the anterior lobe and hyposecretion of the posterior lobe at the same time.

THE ADRENAL ORGANS

This gland is situated on the upper and anterior surface of the kidney. It is surrounded by a capsule and consists of a cortex or outer zone and medulla or central portion. The cortex and medulla are sharply differentiated both in general appearance and in histological structure. The cortex cells contain lipoid granules whereas the medulla is vascular and contain granules known as chromaffin. Physiologically we may divide the suprarenal glands into two great systems, i. e., the cortex or interrenal system and the medulla or chromaffin system. The latter is a part of the large chromaffin system which tissue is spread over various parts of the body.

The suprarenal cortex seems to have a peculiar influence over the functions of the gonads and it is intimately connected with the development of secondary sex characteristics. It influences directly and indirectly somatic and psychic development. The cortical lipoids have been found capable of fixing and neutralizing toxins. It forms a depot for cholesterol which is one of the most important substances in the defence of the body against infection. It has also a tonic effect upon heart muscle. Subsidiary interrenal rests are found in other parts of the body also. Hyperfunction or overabundance of cortical tissue gives rise to pseudohermaphrodism, premature puberty, suprarenal hirsuties and virilism in later life.

The medulla secretes adrenalin, adrenin or epinephrin. Normally these hormones seem to be the regulators of the body emotions stimulating the autonomic, parasympathetic or vagotonic system which is antagonistic to the sympathetic. Thus we get a slowing of the heart beat and a more vigorous and rapid contraction of the heart from adrenalin. It raises blood pressure through its contractile influance over the arterioles. It dilates the pupils. The inhibitory fibres of the intestinal walls or splanchnic fibres are stimulated and hence we get relaxation. This together with pituitrin seems to control gastroenteric muscular action. It improves the general tone of the body because of its regulating influence upon the autonomic system. It has also an influence upon the sugar regulating mechanism and indirectly upon sugar metabolism. In the blood it gives rise to leucocytosis, first increasing the lymphocytes and later the polynuclear neutrophiles. It has also oxygen combining powers with the albuminous material in the hemoglobin and blood plasma. This adds to its antitoxic and body defence properties. As a calcium absorber it is helpful with parathyroid in tetany and enters as a factor in normal dentition. It also stimulates the liver to an abnormal production of catalase. It is used hypodermically injecting 0.5 c. c. of 1:1,000 sol., to determine early hyperthyroidism (Goetsch). In beginning chloroform narcosis there is a rapid stimulation of the chromaffin system which is quickly followed by exhaustion and diminished adrenalin secretion and often collapse. This suggests the administration of adrenalin before giving chloroform inhalation. Cases of postinfluenzal psychosis were improved with adrenalin. Hyposecretion of adrenalin is known to give rise to hyperchlorhydria and predisposes to gastric ulcer. It has also been observed that overactivity of the vagus ofttimes stimulates the adrenal medulla to hypersecretion which in turn balances the vagus irregularity. This secretion is vital to the life of the organism especially because of its action upon the cardiovascular and autonomic systems. An overdose may cause death through diminished lung expansion, excessive congestion and consequent pulmonary edema and not bronchial constriction. Its exhaustion gives rise to marked asthenia.

PINEAL GLAND

This small reddish gray body is placed immediately above and behind the posterior commissure and between the anterior corpora quadrigemina on which it rests. It reaches its greatest development

about the seventh year and after puberty it undergoes involution until it becomes a fibrous band. Its follicles contain a viscid fluid and sabulous matter called bran sand. Physiologically its secretion lowers blood pressure, restrains overfunction and development of the genitals and influences growth and muscular tone in the young child.

THYMUS

It is an organ of fetal and extrauterine life, reaching in man its greatest development at the end of the second year. After this age it undergoes a slow retrograde change until in the twentieth year scarcely a vestige of glandular tissue remains. Formerly it was thought that the gland reaches its maximum size at birth and afterwards undergoes atrophy, so that it is entirely absent in adult life. More careful investigations show that the gland retains its size and presumably its full activity until the period of puberty. It then undergoes a gradual atrophy but some remnants of the gland tissue remain throughout life.

The physiology of the thymus is rather obscure. It is in some way concerned with the processes of growth and in early life influences body metabolism. Similar to pineal gland it restrains sexual function and development to excess. There is some sort of reciprocal relation between the thymus and the reproductive glands. The removal of the thymus in young dogs retards bone growth and induces a condition similar to rickets. It is concerned in the synthesis of nucleic acid and phosphorus metabolism. Because of this the thymus is helpful in cases of malnutrition, rickets, marasmus, osteomalacia, other osseous disorders and mental development.

GONADS

The organs of reproduction have a remarkable influence upon general metabolism and tissue oxidation; regulating muscular tone; stimulating the spinal centres and central nervous system; improving mental and physical vigor. The Leydig cells are functionally united with the sperm cells and undergo considerable development prior to spermatogenesis. Puberty is an endocrine event in which the secretions of the genital glands, the hypophysis, thyroid and the suprarenals take part as excitants of the sexual development, while the thymus and pineal glands act as inhibitors. The harmonious action and interaction of the endocrine system determines the successful pubertal development. The gonads have a specific influence upon sexual characteristics and sexual appetite. It influences catabolism of fat; hair growth and distribution; development of the bones by virtue of influencing calcium excretion and mineral metabolism; the larynx and character of the voice; mentality and assimilation of carbohydrates. The prostatic extracts seem to cause contractility and muscular tonicity of the vas deferens and seminal vesicles.

Ovarian secretion favors oxidation of phosphorized organic substances, hydrocarbons and fats and increases the hemoglobin content of the blood. It also stimulates diuresis, excretion of urea, phosphorus and calcium salts, blood pressure is raised, heart action and respiration are slowed.

The corpora lutea are formed after the discharge of the ovum in the Graafian follicles, the lining of which forms folds and becomes permeated with blood channels. When pregnancy occurs, the epithelium of the Graafian follicle proliferates, its cells increase in size and become filled with yellowish granules—the corpora lutea. Lutein seems to influence mammary development and menstrual disorders. It is useful in excessive or irregular flow. When one frequently aborts, lutein will help considerably to continue the pregnancy to term by restraining pituitary and ovarian influence over the uterine muscle and ovum fixation and hence permitting the ovum to remain fixed and the uterine muscle quiescent.

PARAGANGLIA GLANDS

Under this head are grouped certain small ductless glands and small groups of cells which are closely associated both anatomically and embryologically with the sympathetic system. Their secretions are similar to adrenal medulla and actually a part of the chromaffin system. These are the carotid; coccygeal body or Luschka's gland; tympanic gland and the parasympathetic organ of Zuckerkandl. There are other organs I may call ductless gland appendages which have also an internal secretion as the liver, in glycogenic function; pancreas in sugar metabolism; the spleen as a hemopoietic organ and lymph glands assisting the thymus.

METABOLIC PHASE

Metabolism involves all those changes that occur in our foodstuffs from the time they are absorbed from the alimentary tract until they are eliminated from the organism. In many of these processes the oxygen absorbed from the lungs plays an important rôle. Sajous has shown that the adrenal medulla and thyroid are active in this process of taking up this oxygen and distributing it to the various tissues of the body through the intermediary of the blood.

PROTEIN METABOLISM

Thyroid extract increases nitrogen output and helps materially protein metabolism. Posterior pituitary lobe, increases tissue fat utilization power and thereby is protein sparing and also influences protein metabolism. Adrenalin, by stimulating the former two, indirectly influences protein metabolism. The process of deaminization of the excess of aminobodies is accomplished by the liver as by the body itself.

FAT METABOLISM

The essential nutritive value of the fats is that they furnish energy to the body and, from a chemical viewpoint, they must contain more available energy than the protein or the carbohydrates. The pituitary, thyroid, gonads, pineal, thymus and adrenals influence fat metabolism and regulate its distribution over the body.

CARBOHYDRATE METABOLISM

The available carbohydrate material of the body consists of the glycogen found in the tissues, especially in the liver (one to four per cent.) and in the muscles 0.5 per cent. The sugar formed from this glycogen and present constantly in the blood is 0.1 per cent. to 0.15 per cent. During starvation the glycogen and sugar are obtained from proteins and fat of the body. The regulation of the sugar supply of the body is a matter of the greatest importance.

The ductless glands, as the evidence shows, are most concerned in these processes. On the one hand we have the subsequent reconversion of this glycogen to sugar (glycogenolysis) according to the needs of the body. On the other hand we have the processes of consumption of sugar in the tissues for energy purposes (glycolysis). These processes may be accelerated or retarded by the action of the hormones arising in the ductless glands. The pancreas and liver are greatly concerned in this mechanism. The thyroid, pituitary and the gonads influence it. The adrenals stimulate the processes.

THE INORGANIC SALTS

The body contains in its tissues and liquids a considerable amount of inorganic material. There can be no doubt, in fact, that each one of the salts of the body has a special nutritive value and a special metabolic history. Including the bones, the average amount of ash in the body is about 4.4 per cent. of its weight. The bones contain most of it, about five sixths in the adult and, less in a child, in which the proportion of animal matter is much greater. In muscles there is about 0.6 per cent. of its moist weight. The ash is made up of phosphates, chlorides, sulphates, carbonates, iodides, fluorides, and silicates of potassium, sodium, magnesium, iron and calcium. In the body fluids the main salts are sodium chloride, sodium carbonate, sodium phosphate and potassium chloride. They maintain a normal composition and osmotic pressure in the liquids and tissues of the body, and, by virtue of their osmotic pressure they play an important part in the composition of living matter. In childhood and adolescence all the calcium that can be obtained is required for growth. The metabolism of calcium appears to be regulated by the ductless glands acting together as a group. The calcium is found in the body in two forms: 1, Fixed in the tissues helping to build up the frame work of the body, and 2, floating calcium, ready to be called upon when required. Calcium also regulates muscular contraction and when in insufficient quantity, effusions of lymph into the tissues take place. The thyroid, parathyroid, adrenal medulla, anterior pituitary and thymus act as calcium absorbers or retention; whereas adrenal cortex, posterior pituitary and the gonads are calcium excretors.

TEETH

The function of the teeth in children is so important for the act of chewing and preparing the food bolus for deglutition, that proper digestion and normal metabolism of foods are entirely dependent upon it. And indirectly body and mental growth is dependent upon it and so healthy teeth are essential. When the correct balance between intake and output of calcium salts is upset as in some children, and the loss is great the enamel of the teeth will begin to break down, and the alkalinity of the saliva diminish. Then caries sets in with further destruction of enamel and dentin. This will be followed by the accumulation of food particles within, bacteria nests occur followed by fermentative action in the carbohydrate medium of food recesses, in which acid solvents are generated and more destruction and infection of the teeth. Early attention to improper functioning ductless glands may overcome these defects. It is therefore correct that the calcium content of the saliva and the blood can be increased by suitable pluriglandular therapy, and that this calcium can be laid down as fixed lime in the teeth.

The internal secretions have also a certain favorable influence upon the dental tissues proper, by bringing about normal eruption; cause sufficient calcification previous to eruption; increase calcification after eruption; concerned in the prevention of caries through the alkalinity of the saliva as already mentioned and arrest decay should caries supervene; and, possibly by means of a trophic action keep the tooth tissue in such a healthy state as to resist caries.

CONCLUSION

I wish to emphasize the fact that after offering a comprehensive survey of the anatomical and physiological considerations of the ductless glands to the reader, he should be in position to be able to differentiate endocrine disorders from other ailments. When applying this knowledge in a practical way to overcome physical or mental abnormalities therapeutically, it must be understood that the administration of ductless gland products should not be construed as the cureall for every disease. And as stated, neither is every complaint, pathological state, mental aberration and every functional and organic deviation from the normal an internal secretory disturbance. Climate, dietetics, vaccines, serums, drugs, lipoids, vitamines, massage, electrotherapy, hydrotherapy and calisthenics and other measures each have their own usefulness and often act synergistically with the ductless glands when indicated and employed together. A meagre knowledge of these fundamentals and the careless administration of endocrine therapy may make out of it a fad or belittle a rational form of therapy of the utmost value to the human economy or organism.

182 Lexington Avenue.

The Thyroid Apparatus in Man.—G. Scott Williamson (*Lancet,* December 22, 1923) believes that the thyroid gland, the parathyroid bodies and the thymus are intimately related anatomically, physiologically and pathologically. They are probably engaged in the conduct of some specific function. The thyroid gland is the main organ. The parathyroid is a sentinel gland of neurolymphatic nature, set in the course of the effluent, probably engaged in measuring the efficiency of the thyroid gland, and through the sympathetic nervous system adjusting its operation to the needs of the body. The thymus is a reservoir for the effluent—which, according to its nature is stored either as fat or in the lymphocytes. This must not be taken to imply a movement of lymphocytes into the blood or lymph; the lymphocytes are probably manufactured and absorbed *in situ.* The fact that colloid usually disappears to give place to any secretory activity, and the fact that it need not be associated as in marasmus and in early fetal active glands, make it probable that the colloid is exercising some vehicular function analogous to some constituents of the bile. It is only passively concerned in the operation of the thyroid apparatus.

Certain preliminary chemical studies fix upon nitrogen carriage as the significant function of the lymphocyte, and this from the point of view not so much of total nitrogen as of the nature of nitrogen.

The Surgical Treatment of Hemorrhage from Gastric and Duodenal Ulcers*

HERBERT J. PATERSON, C.B.E., M.C., (Cantab.), F.R.C.S.,
London

CLASSIFICATION OF HEMORRHAGES

The surgical treatment of hemorrhage from gastric or duodenal ulcers may be discussed in reference to two distinct groups of cases, the sudden acute hemorrhages, so severe as to threaten life itself, and the chronic or recurrent hemorrhages, less alarming in extent but by their repetition tending to produce a serious and profound anemia, which, if unchecked, may ultimately prove fatal.

From a surgical point of view this classification seems preferable to that in which a distinction is drawn between hemorrhage from a socalled acute ulcer and hemorrhage from a chronic ulcer, and this for two reasons. First, we do not know that there is such a pathological distinction, the existence of an acute ulcer is purely conjecture, and secondly, if such distinction there be we cannot recognize it clinically. The duration of symptoms has no relation to the chronicity of an ulcer as seen in the operation theatre.

ACUTE HEMATEMESIS

I am well aware of the danger of laying down hard and fast rules. To do so may give those who come after us cause "to reflect on the vanity of received opinion"—nevertheless I have formed very decided views as to the wisdom of surgical intervention in cases of acute hematemesis, which I may express in a single sentence. The subject for discussion is the surgical treatment of acute hematesis. There should be no such thing. Operation during the progress of or shortly after a gastric or duodenal hemorrhage is a delusion and a snare, and in my judgment should never be attempted.

Acute hematemesis is one of the unappropriated blessings still remaining for the physician. It is not a condition which lends itself to operative measures. The collapse induced by loss of blood is favorable for the arrest of hemorrhage but unfavorable for surgical intervention. Usually, it can be arrested by medical treatment, and if this fail, surgical interference is not likely to help matters. By subjecting such patients to operation, we expose them to added dangers, which may just turn the scale against them, whereas without operation the probability is that they will recover. I shall endeavor very briefly to give reasons for the faith which is in me.

In discussing this subject two questions must be answered. 1. What is the mortality rate from hemorrhage in cases treated medically? 2. What is the mortality rate in the cases treated by immediate operation?

MORTALITY RATE FROM HEMORRHAGE IN CASES TREATED MEDICALLY

Most clinicians are agreed that the mortality rate from hemorrhage in cases of gastric and duodenal ulcer treated medically is under five per cent. In the four series of cases given in Table I the mortality rate is 3.8 per cent.

TABLE I.

Recorder	No. of Cases	Mortality Rate
Lenhartz	201	3 per cent.
Ewald	166	4.8 " "
Wirsberg	320	5.9 " "
H. P. Hawkins	556	0.7 " "
	1243	3.8 " "

MORTALITY RATE FROM HEMORRHAGE IN CASES TREATED BY IMMEDIATE OPERATION

The last published statistics I can find are those of Lindberg (1). He tabulates eighty-three cases with thirty deaths, a mortality rate of thirty-six per cent. If I relied on these statistics doubtless the objection would be raised that they are out of date, and that with more modern technic and especially by the use of blood transfusion, the results of operation are far better, at the present time. I am not clear that there is ground for this optimism, but at any rate the results of surgical treatment are still indubitably inferior to the results of medical treatment. Through the courtesy of the surgical registrars of the London hospitals I have ob ained some statistics as to operation for acute hematemesis in recent years and they are shown in Table II. I should like to take the opportunity of thanking most sincerely those who have helped me.

*Being an Introduction to a joint discussion in the Sections of Medicine and Surgery of the Royal Society of Medicine, March 5, 1924.

Obviously it is not fair to compare these figures with the mortality rate from hemorrhage in all cases of ulcer whether they bleed or not. They must be compared with the mortality rate in severe cases of hematemesis. Hemorrhage occurs in at least two thirds of all cases of gastric ulcer, and is severe or recurrent in about thirty per cent. Calculated on this basis the mortality rate of those cases in which there is severe or recurring hemorrhage treated medically would be about eleven per cent. I think this is probably an exaggeration but we shall be well within the mark in stating that of the patients who bleed severely or bleed repeatedly and are treated medically not more than one in nine will die, while of those who are operated on one out of three will probably die.

SOURCE OF BLEEDING

No doubt there are surgeons who by superior skill, aided by a considerable share of luck, may be able to show much better individual results than these. I say aided by luck, for we must bear in mind it is impossible in a given case to predict whether we shall be able to find, let alone deal with, the source of the bleeding. It is inevitable that in a certain proportion of cases the patient will have the added risks of an operation without any effective treatment of the bleeding point. In at least three of the successful cases in Table II no definite source of bleeding was discovered and nothing further could be done. The operation was purely exploratory and therefore an unnecessary complication to the patient's recovery.

TABLE II.

No. of Cases	Deaths	Mortality Rate
19	7	36.8 per cent.

I think this is what we should expect, as I am convinced that bleeding from the ulcer itself is far less common than is imagined. In duodenal ulcer especially the source of the bleeding is a general oozing from the mucous membrane of the stomach—the whole surface appears to be weeping blood—and I have in some cases cut sections of the mucous membrane which showed the blood cells escaping between the epithelial cells of the mucosa.

MEDICAL TREATMENT SAFER THAN SURGICAL

But apart altogether from statistics, I am convinced from my own experience that the treatment of acute hematemesis by medical means is the wiser and safer course. Up to the end of the year 1922 I have had under my care, or jointly with my colleague, Dr. Soltau Fenwick, forty cases in which hematemesis was of such severity that the patients were on the brink of the grave. All of them recovered with medical treatment, indeed I have yet to see a death from hematemesis from a gastric or duodenal ulcer. In all of them operation was delayed for two or three months until the patient had recovered from the effects of the hemorrhage, for I confess I have never yet operated during the course of a hematemesis. These cases are tabulated in Table III.

All the patients were treated medically in the first instance and in all but two gastrojejunostomy was performed at a later date. Of the two exceptions one was a nurse who was anxious to avoid an operation. She was kept in bed for six months and eventually made a complete recovery and had no further hemorrhage. The other case was one of gastrojejunal ulcer in which the ulcer was excised and a new anastomosis performed. Four of the cases are labelled gastrostaxis, as at the operation I could find no ulcer, and I think that the hemorrhage was probably secondary to a diseased appendix. These were among my very early cases and I admit that the performance of gastrojejunostomy in these cases was a totally unnecessary complication of appendectomy.

TABLE III

ACUTE HEMATEMESIS

	Number of Cases	Hematemesis only	Melena only	Hematemesis and Melena	Operation	Recovered from operation	Recurrence of hemorrhage
Gastric ulcer.....	15	9	0	6	14 G.J.*	14	0
Duodenal ulcer.....	20	6	0	14	20 G.J.*	20	1**
Gastrostaxis	4	4	0	0	4 G.J.*	4	0
Gastrojejunal ulcer..	1	0	0	1	Excision	1	0
	40	19	0	21	39	39	1

*Average interval between hemorrhage and gastrojejunostomy=3 months.

**Had slight hematemesis two months after. No further hemorrhage. Died three years later.

In only one of these patients was there any recurrence of hemorrhage. This patient had a slight hematemesis two months after operation, there was no subsequent recurrence up to the time of her death three years later from causes unconnected with her gastric condition. One of the patients was readmitted into hospital a year after his discharge, in a moribund condition from a perforated jejunal ulcer. Thus the immediate operative mortality in this series was nil, and all but two of the patients were apparently cured.

It cannot be emphasized too strongly that patients rarely die of a first hemorrhage, it is the repetition of the hemorrhage which is of such serious import. Let us beware of the specious but fallacious argument which I have heard put forward in connection with these cases. "This patient is bleeding. He will probably die. Something must be done." Even admitting that the premises are true, I see no logical or other reason for the conclusion, that because death is impending, something should be done which will probably make the patient's life shorter still. The case is quite different in acute intestinal obstruction, in which without surgical intervention death is inevitable, and so operation is justifiable even in desperate cases. In hematemesis, on the other hand, operation may be the last straw for a patient who otherwise might recover.

IMPORTANT POINTS IN THE MEDICAL TREATMENT OF ACUTE HEMATEMESIS

As regards the medical treatment of acute hematemesis the important points are:

1. Rest in bed and by this I do not mean what often passes as absolute rest. The patient should be kept *absolutely* still in bed, no movement even of the arms or legs being permitted, and should be fed by hand with a minimum of disturbance.

2. Tripier's hot water injections by the rectum, saline at a temperature of from 120° to 130° F. being used.

3. An ice pack to the abdomen.

4. Nothing should be given by the mouth for at least four days and then feeding should be commenced with teaspoonfuls of iced milk and egg (Len-

hartz). This amount is gradually increased, and the patient is kept on milk diet for two months, when some diluted beef essence may be added to the dietary.

In my experience it is not safe to commence Lenhartz diet directly after a hemorrhage; sometimes I have seen recurrence of hemorrhage apparently brought on by too early feeding. Saline injections with half an ounce of glucose to the pint are commenced soon after the hemorrhage has ceased. Rectal feeding is starvation except so far as fluids and salts are concerned, so that injections of beef tea, milk and the like are valueless.

5. Small doses of morphine are valuable although some clinicians object to the use of morphine on the ground that its use may prevent contraction of a bleeding artery. I imagine this objection to be academic rather than practical.

6. The subcutaneous injection of a ten per cent. solution of sterile gelatine in forty c. c. doses repeated daily.

7. If vomiting or hematemesis continue the stomach should be washed out very gently with warm water, and after the lavage a dose of crystalline bismuth subnitrate should be given through the tube.

It used to be taught that in hemorrhage from the socalled acute ulcer, subsequent operation is unnecessary unless the bleeding recurs. If we could be certain that the ulcer which bleeds is an acute ulcer this teaching would be sound, but as we cannot make such a pathological distinction, the only safe rule is that an acute hemorrhage requires surgical treatment to prevent recurrence. As to the time of the operation, the interval between the hemorrhage and operation should be at least three months, and if the patient is still anemic transfusion of blood before operation is a valuable adjuvant.

CHRONIC OR RECURRENT HEMATEMESIS

As regards the treatment of the chronic or recurrent hemorrhages operation should as a rule be deferred for two or three months after the last hemorrhage, according to the condition of the patient, medical treatment being carried out in the meantime —rest in bed, Lenhartz diet, saline and glucose injections by the rectum and gastric lavage. It must be borne in mind that in large excavating ulcers septic processes in the ulcer may play a considerable part in causing the hemorrhage, so that it is important not only to rest the stomach but to keep it clean. Usually these measures can be relied on to prevent recurrence, but even if the hemorrhage is repeated I wuold persevere with medical treatment. If in spite of absolute rest there is further recurrence, the question of operation may be considered, but—and this is the important point—absolute rest must have been tried and failed. Although personally I have never had to depart from my usual practice of delaying operation for two or three months, if in spite of a thorough trial of medical treatment there were many small losses of blood or more than one hemorrhage of such severity as to cause obvious anemia, I should not hesitate to operate before the onset of another attack. But my experience is that efficient medical treatment does not fail. If, however, operation be decided upon it should be preceded by blood transfusion.

NATURE OF OPERATION

There will probably be considerable difference of opinion as to the nature of the operation which should be performed for recurrent hemorrhage. Various procedures have been adopted, such as ligature of arteries, gastrojejunostomy, resection of the ulcer, cauterization of the ulcer combined with gastrojejunostomy, and partial gastrectomy. Personally, I still pin my faith to gastrojejunostomy; so far it has not played me false.

It would be outside the limits of this discussion to compare the relative merits of gastrojejunostomy and partial gastrectomy in the treatment of ulcer, but this much may be said that hemorrhage is not an indication for resection. If more than gastrojejunostomy be considered advisable, infolding the ulcer or cauterizing it by the Donald Balfour method is safer and equally as efficacious as resection. Resection has its place in gastric diseases, as in disorders in other parts of the body, but among thoughtful surgeons there is undoubtedly a feeling that this practice is being carried too far. "If your colon offends you—cut it out." If the gallbladder suggests a strawberry, cut it out, and some surgeons advise removal of a considerable portion of the stomach even for a duodenal ulcer. It would seem as if the perfect man of the future will be one who has had all his removable organs cut out and all his irremovable ones stitched in. There is bound to be a reaction against this fashion of "cutting out" when simpler means may suffice.

GASTROJEJUNOSTOMY THE SIMPLEST PROCEDURE

Some object to gastrojejunostomy on the ground that it is an indirect method of treating hemorrhage. Doubtless to deal with the bleeding point is the ideal, but it is rarely practicable. That we must look our enemy in the face is an aphorism that sounds well, but one which if applied to the treatment of gastric hemorrhage may lead to injudicious surgery. In the great majority of cases gastrojejunostomy may be relied on to prevent further hemorrhage from a gastric or a duodenal ulcer; it is the simplest surgical procedure to adopt, and it has the great advantage that we start with a definite plan in view, and so are not tempted to do an extensive exploration which may just turn the scale against the recovery of the patient. If it fail it is time enough to adopt more drastic measures. In some at least of the cases in which gastrojejunostomy has been unsuccessful the suggested alternatives would prove equally ineffective. I recall the case of a lady on whom I performed gastrojejunostomy for duodenal ulcer with recurrent attacks of hematemesis. Some years after the operation she had several recurrences. Believing that the duodenal ulcer was unhealed I reopened the abdomen, the ulcer was completely healed, but as a precautionary measure I infolded it. She continued to have attacks of hematemesis at intervals, and some years later I again opened the abdomen and explored the interior of the stomach but could find nothing to account for the bleeding. She still has attacks of hematemesis and melena occasionally, which I take it are of intestinal origin, and so would not be cured by gastrectomy.

I have had under my care or jointly with my colleagues, Dr. Fenwick and Dr. Porter Parkinson,

eighty-four cases in which there were recurrent attacks of definite and severe hematemesis. These are tabulated in Table IV.

TABLE IV.

CHRONIC OR RECURRENT HEMORRHAGE

Kind of ulcer	Number of Cases	Hematemesis only	Melena only	Hematemesis and melena	Operation	Recovered	Died[1]	Recurrence
Gastric ulcer.....	26	22	4	0	G.J.	25	1	0
Duodenal ulcer.....	52	32	4	16	G.J.	50	2	6
Gastric and Duodenal ulcer.....	4	4	0	0	G.J.	4	0	0
Gastrojejunal ulcer..	2	2	0	0	Excision	1	1	0
	84	60	8	16	84	80	4	6

[1]Four deaths, one from exhaustion, one from pulmonary embolus, and two from pneumonia.

In eighty-two of these the hemorrhage was due to a gastric or duodenal ulcer and in all of these gastrojejunostomy was performed. There were three deaths in this series, so that adding the thirty-eight cases of gastrojejunostomy given in Table III there were three operative deaths in 120 operations, a mortality rate of 2.5 per cent., which although rather higher than the death rate of gastrojejunostomy in an ordinary series of cases, cannot be considered high in view of the condition of some of the patients. Six of the patients had some recurrence, to one of these I have already alluded. Another patient had phthisis of which he died five years after operation, and it was not certain whether he had hemoptysis or hematemesis. In only one of the remaining four patients was there more than one slight attack. So that in the whole series of cases, 2.5 per cent. of the patients died from operation, in 4.2 per cent. there was a recurrent hemorrhage of a trivial character, and in ninety per cent. no further hemorrhage occurred after the operation of gastrojejunostomy. I submit that these figures justify the treatment adopted.

The treatment of acute hematemesis is one of the most absorbing and fascinating problems of medicine—absorbing from the satisfaction it affords when we see a patient literally snatched from the very jaws of death, and fascinating because it demands supreme courage—courage to perform that most difficult task of waiting and watching. When by the bedside of a patient so blanched by hemorrhage that death is painted on her face, whose flickering pulse is witness to the slender thread on which life hangs, it is not easy to resist the insistent question of the relatives, "Cannot something more be done?" To answer in the negative requires no little courage. It is easy to do something, but if that something be an operation, we shall probably have an opportunity of wondering at leisure what would have happened if this operation had not been done.

Some of you remember how, shortly before the war, the passengers from the burning ship *Volturno* were rescued in midatlantic by Captain Barr of the Cunard liner *Carmania*. At first the sea was so rough that in spite of the urgent appeals, not only of the passengers but of his officers, Captain Barr resolutely refused to allow volunteers to man the boats until the gale had died down. He stood by the doomed ship for two days and eventually all the passengers and crew were rescued except a few who had jumped overboard in a state of panic.

We came home from America by the *Carmania* on her next voyage. One evening at dinner one of the passengers was criticizing Captain Barr and suggested that he might have acted sooner than he did, and he appealed to one of the stewards to confirm his opinion. "I think, sir," replied the steward, "that it was fortunate that there was one cool head on this boat or a good many lives would have been lost that day." It was a worthy tribute to a fine example of supreme moral courage. Captain Barr told me that it was the most difficult and trying situation he had ever faced, to resist the appeals to attempt to save the lives of those who otherwise seemed doomed to a watery grave. By the result his judgment and his courage were vindicated.

Inaction is often the wisest and only safe course, but it is always the more difficult. Anyone can try to do something, knowing that although he fail he will be applauded, even if the failure be at the sacrifice of human life; but it is the strong man who refuses to be tempted into taking risks which he believes can serve no useful purpose.

In conclusion, if I may be permitted to offer one word of advice to my younger hearers it is this. When called upon to treat a patient with hematemesis, take your courage in both hands and trust Nature. Be assured that if you trust her and assist her, she will not fail you, and your reward will be that which always seems to me the greatest satisfaction that the practice of our art can give, the knowledge that you have steered a frail bark back to safety without encountering the perils incidental to the handicraft of our art.

CONCLUSIONS

1. Hemorrhage from gastric and duodenal ulcers may be considered in reference to two distinct groups of cases, the sudden acute hemorrhages and the chronic or recurrent hemorrhages.

2. Surgical measures have no place in the immediate treatment of acute hemorrhage.

3. In the medical treatment of gastric or duodenal hemorrhage *absolute* rest is a most important factor.

4. When the patient has recovered from the resulting anemia operation should be performed to prevent recurrence. The interval between the hemorrhage and operation should be at least three months.

5. In the first instance the chronic or recurrent hemorrhages should be treated medically, operating when the patient's condition is favorable.

6. Regular gastric lavage pending operation is an important detail of the medical treatment of the chronic or recurrent hemorrhages.

7. As regards operative measures, gastrojejunostomy is the simplest and safest procedure, and in the great majority of cases may be relied on to prevent recurrence of the hemorrhage.

8. Careful and prolonged medical treatment *after* operation is equally as important as medical treatment *before* operation.

9. With this combination of medical treatment followed by gastrojejunostomy the mortality rate from hemorrhage in gastric or duodenal ulcers should not exceed four per cent. and freedom from recurrence may be expected in ninety per cent. of the cass.

Carcinoma of Rectum and Rectosigmoid

FRANK C. YEOMANS, M.D., F.A.C.S.,
New York

According to statistics, carcinoma of the rectum or rectosigmoid comprises about four per cent. of all malignant growths of the body. In the gastrointestinal tract the stomach is involved most frequently, but approximately eighty per cent. of all intestinal cancers are in the rectum or rectosigmoid.

The urgent call of the cancer therapist is for early diagnosis. The campaign of the American Society for the Control of Cancer, by popular education in the early symptoms of malignant disease, is showing results, especially in external growths and notably in carcinoma of the breast. In internal cancer, however, as a rule there is at first no tumor or local change visible to the patient, and the early symptoms are vague. This is particularly true of malignant disease of the large bowel. We might well speak of the "silent" rectum so far as any outspoken symptoms manifest themselves early. This is in the nature of a disease so insidious as cancer, which may remain almost symptomless for many months and eventually force the patient to consult a physician for symptoms of marked ulceration or obstruction.

SYMPTOMATOLOGY

The classical symptoms of carcinoma of the rectum, as originally written and handed down with little variation from one textbook to another, are largely a story of terminal pathology. This chapter must be revised and the *early* symptoms stressed if any efficient educational stimulus is to stir the laity and the profession to a recognition of beginning malignancy. Evidence of the need of this teaching is the fact that six to eight months is the average period of time from the onset of the first symptoms till the patient reaches the surgeon.

The material of this paper comprises 110 cases of carcinoma of the rectum or rectosigmoid, in all of which I examined and studied the patients thoroughly and operated upon many of them. There were eighty males and thirty females.

AGE INCIDENCE

	Male.	*Female.*	*Total.*
10 to 19 years.....	1	0	1
20 to 29 "	5	0	5
30 to 39 "	6	4	10
40 to 49 "	16	10	26
50 to 59 "	28	10	38
60 to 69 "	14	6	20
70 to 79 "	10	0	10

Of the total number, sixty-four patients, or fifty-eight per cent., were of the socalled cancer age of forty to sixty years; thirty, or twenty-seven per cent., were over sixty years of age, and seventeen, or fifteen per cent., were under forty years. The youngest patient was a youth, aged nineteen, with colloid carcinoma. Three cases in persons under seventeen years have been reported, viz., Kupferle (Czerney's clinic), one aged thirteen, and Schneider (Rostocker clinic) two cases in persons aged, respectively, fourteen and fifteen years. Thus it is evident that age *per se* is not a diagnostic point in an individual case.

WEIGHT LOSS

Loss of weight averaged eighteen pounds in this series. One patient had lost sixty pounds, but several patients had not lost any weight. Emaciation is, in fact, a late symptom of carcinoma, and maintenance of weight for several months after its onset does not exclude the disease.

PAIN

Exquisite pain is a cardinal symptom of epithelioma of the anus, but, in general, in rectal carcinoma, as usually situated, pain is not pronounced unless the growth is very low, or until it has extended widely, or has caused marked obstruction. Frequently, however, there is a feeling of fulness in the pelvis, of pressure and obstruction in the rectum, and often colic at stool. Anemia and weakness develop in the later stages of the growth, and are signs of an advanced process.

WASSERMANN REACTION

The Wassermann test of the blood should be made in every case of tumor, stricture, or ulcer of the rectum. It was positive in seven cases of this series. The simultaneous occurrence of syphilis and cancer is, therefore, not unusual and warns us to be on our guard lest we mistake cancer for syphilis of the rectum as well as the development of cancer on a syphilitic soil.

DURATION OF SYMPTOMS

The onset was gradual in seventy-seven cases and sudden in thirty-three. The duration of symptoms had averaged six months for the males and 7.8 months for the females. Three weeks was the shortest period, but in several cases it was eighteen months. Meanwhile, a few of these patients had not consulted a physician, but the majority had done so and the condition had been diagnosed and treated as stomach trouble, indigestion, constipation, chronic colitis, bloody dysentery, tuberculosis of the rectum, bleeding polyp, anal fissure (three cases), hemorrhoids, rectal fistula, carcinoma of the prostate and retroversion of the uterus. Hemorrhoids was the favorite diagnosis, and several patients had been operated upon only recently for this condition and two for anal fissure, although the growth was then present and palpable. It is, indeed, regrettable to note that the reports of different series of cases indicate that the disease, until far advanced, is regarded as hemorrhoids in from ten to fifty per cent. of cases.

What, then, are the symptoms of beginning carcinoma of the rectum and rectosigmoid? Careful inquiry in 110 cases showed the first symptom to be constipation in sixty-eight cases, or sixty-two per cent.; second, bleeding or cancer diarrhea, in thirty-seven, or thirty-three per cent., and pain in the remaining five per cent. In the latter it should be noted that the anal canal was involved. Bowel action was stated as regular in six cases, but in the great majority there was obstipation although there were frequent passages of discharge (cancer diarrhea). In-

digestion, often accompanied by nausea, was an almost constant associated early symptom.

When the ulceration and secondary infection of the second stage develop, frequent foul discharges of mucus, blood and pus occur, constituting the socalled cancer diarrhea, although the patient is still really constipated. Finally, the late symptoms of intestinal obstruction may supervene.

Anemia, emaciation and weakness are not characteristic of the first stage, but are progressive in the second and third stages, when the cachectic patient himself suspects the true nature of his malady and is probably hopeless for curative surgery.

There is, in fact, no one symptom of early carcinoma of the rectum and sigmoid colon that is pathognomonic, but an attack of obstinate constipation in a person with usually normal bowel action, desire to go to stool in the morning on arising, with no result or only the passage of flatus and a little mucus, probably bloodstreaked; an abnormal rectal discharge and a vague, ill defined feeling that something is radically wrong in the lower abdomen, or a feeling of obstruction in the rectum, form a symptom complex that is present in nearly every case of beginning carcinoma of the sigmoid and rectum. When such a complex is elicited by close inquiry, it becomes our duty to make a thorough examination. Failure to make the examination, or to see that it is made, is a serious dereliction of duty.

PHYSICAL EXAMINATION

The physical examination is both general and local. If the patient gives a history of cancer diarrhea and marked obstipation, is emaciated, weak and anemic, he is probably already in the stage of terminal pathology and not of surgery. Jaundice, ascites and a visceral tumor, especially of the liver, indicate hopeless metastases. The sigmoid colon is often more prominent than normal, and the masses, sometimes felt in the left lower quadrant of the abdomen and higher on the left side, usually prove to be scybala. If the inguinal glands, which receive the lymphatic drainage below the anorectal line, are involved, recurrence will probably follow operation.

The local examination includes palpation, proctosigmoidoscopy, biopsy and the röntgen rays. In women a vaginal examination should be made first to determine the position of the uterus, and the condition of the culdesac. As a rule, digital examination of the rectum is made with the patient in the Sims's position; but a growth not otherwise palpable may sometimes be felt with the patient in a squatting posture or under general anesthesia, by making counterpressure on the abdomen.

In this series of 110 cases the tumor was palpable in ninety-nine so that in only eleven cases, or ten per cent., was the proctoscope essential to determine the presence of a growth at a higher level. The tumor involved the anterior rectal wall in thirty-nine cases, the posterior wall in thirty-three cases, was lateral in seven and annular in thirty-one. The growth felt movable in sixty-two cases and fixed in forty-eight. In the majority the neoplasm was ulcerated, and in ten cases infiltrated adjacent organs. The segment of bowel directly involved in the growth varied from five to ten cm. in length. Clinically the growth proper may be:

1. Protuberant, that is, growing into the bowel lumen, of small or large size, superficially ulcerated, and movable with the mucosa. This type is relatively benign in that few or no lymph glands are involved.

2. A craterlike, excavated growth, with indurated base and nodular margins, infiltrating the musculature and penetrating the lymphatics early.

3. An annular, constricting growth, occurring especially at the rectosigmoidal juncture, rather definitely limited to the bowel wall and tending to produce early stenosis.

These details of size, form, position, mobility or fixity, and ulceration of the growth, involvement of adjacent organs and metastases, are all prime factors of prognostic import. For lesions beyond reach of palpation, the modern pneumoelectric proctosigmoidoscope becomes an elongated finger with a human eye. By this instrument of precision the examiner can readily inspect the entire rectum and anal canal and, in approximately seventy-five per cent. of cases, the distal loop of the sigmoid colon. No anesthetic is employed, but skill in passing the instrument and correct interpretation of the findings are to be acquired only by extensive experience. The graduated tube of one half inch calibre can usually be passed through a stricture or beyond a tumor to the normal mucosa above, thus determining precisely the length of the process. Constriction by the growth prevented the passage of the tube in only twelve cases of this series.

BIOPSY

In accessible growths of the terminal colon, frank carcinoma that can be seen or felt is so characteristic in its appearance and feel to the experienced examiner that biopsy for diagnosis is unnecessary. There are, however, certain cases of tumor, stricture and indurated ulcer that baffle the diagnostic acumen of the most experienced. I know of two instances, at least, in which the rectum was removed (one by myself and another by a colleague) for presumable carcinoma, but careful histological study of the specimens demonstrated only chronic inflammation. Hence, in these cases of doubtful diagnosis, I believe in and practise biopsy to solve the problem at once. Some years ago I devised a specimen forceps for use through the proctoscope which is practical and satisfactory. Biopsy is performed, when indicated, as part of a routine examination in the office, without anesthesia and without alarm to the patient. I am aware of the objections raised to biopsy, viz., hemorrhage, infection, bowel perforation and possibly dissemination of the growth, if it is malignant. When biopsy is performed correctly, bleeding, infection and perforation do not occur. As to the dissemination of cancer cells, I have seen no clinical evidence of it and question its occurrence more rapidly than normal if biopsy is followed by immediate cauterization of the wound.

In this series of 110 cases, biopsy was performed in thirty-four. The diagnosis was adenocarcinoma in twenty-five cases, epithelioma in four, colloid carcinoma in two, malignant adenomatous polyp in two, and angiosarcoma in one case.

RÖNTGEN RAYS

There is a growing tendency among medical men, when the symptoms indicate rectosigmoidal pathology, to refer the patient at once to the röntgenolo-

gist. This substituting, in an accessible field, the indirect laboratory method for direct palpation with the experienced finger and inspection with the intelligent eye is, in my opinion, a step backward in diagnosis. For the diagnosis of lesions of the rectum, radiograms are, as a rule, not only unnecessary but may be misleading; for the growth is often missed. Palpation and proctosigmoidoscopy, with a biopsy in certain cases, furnish all the precise data required. For lesions of the distal sigmoid, in the seventy-five per cent. of cases in which the tube will negotiate the rectosigmoidal angle, the sigmoidoscope supplies accurate and reliable information. Nevertheless, in all cases of tumor, stricture and indurated ulcer of the bowel without urgent symptoms, such as obstruction, radiograms should be obtained to detect, if possible, other or similar lesions, sometimes present, beyond reach of the tube. Carmen states that seventy-five per cent. of tumors of the colon can be detected by the x ray.

DIFFERENTIAL DIAGNOSIS

Anal fissure.—At its onset epithelioma of the anus closely simulates a painful fissure or irritable ulcer of the anus both in its symptomatology and its appearance. Bidigital examination, however, detects the deep, hard induration characteristic of epithelioma and, if there is serious doubt, immediate biopsy should be done.

Hemorrhoids.—Carcinoma is frequently accompanied by hemorrhoids which too often are diagnosed as the only lesion present. Hemorrhoids should never be treated before examination of the rectum to eliminate other pathology.

Thrombosis.—Thrombosis of the rectal veins usually occurs in men with sclerosed vessels. The veins may rupture and bleed profusely, and to palpation suggest a neoplasm. Proctoscopy is our surest means of recognizing them.

Ulcer of rectum.—Large, nonsyphilitic, indurated ulcer of the rectum may, under inspection and palpation, so resemble beginning carcinoma that only a biopsy can differentiate it, as in the two cases noted heretofore.

Chronic inflammations.—Of the chronic inflammations, syphilis manifests itself here either as a tertiary ulcer or its sequel, a stricture. A history of infection and a positive Wassermann reaction are most helpful in deciding if we remember that the lesion may also be carcinoma in a syphilitic.

Tuberculosis, the other principal chronic inflammation, may be present as, 1, a tuberculous ulcer of the rectum; 2, a tuberculoma or hyperplastic tuberculosis, which in all respects resembles a protuberant carcinoma and can be differentiated only by biopsy; 3, tuberculous mesenteric glands which, before suppuration, feel like a rectal tumor but tuberculosis will be found elsewhere in the body, and 4, plastic tuberculosis of the culdesac of Douglas.

Mucous polyp.—This is a large, solitary, histologically benign growth usually situated in the rectosigmoid. It produces bowel and general symptoms like carcinoma, but can be differentiated readily by sigmoidoscopy.

Multiple adenomata.—In this condition literally thousands of small growths, some pedunculated but the majority sessile, stud the mucosa of the colon and rectum and are to be recognized by proctosigmoidoscopy. If neglected, multiple adenomata usually undergo malignant change into adenocarcinoma, therefore, early recognition and appropriate treatment are essential.

Diverticulitis.—This practically never occurs in the rectum, but is relatively common in the sigmoid. The symptoms of acute diverticulitis are those of acute appendicitis transferred to the left side, but chronic diverticulitis with slow infiltration and thickening of the bowel wall and mesentery resembles malignant disease. Aside from laparotomy, röntgenograms are of the greatest aid in its diagnosis. In the days before the advent of the x ray and before the pathological examination of all specimens removed at operation was a routine measure, many cases diagnosed at laparotomy as carcinoma of the sigmoid, which receded after colostomy, were undoubtedly chronic diverticulitis.

Primary carcinoma of the prostate.—Rectal palpation detects the asymmetrical enlargement, nodular, hard surface and the fixation of the gland, and usually the mobility of the rectal mucosa opposite. The urological symptoms will, of course, help to differentiate.

Douglas's culdesac.—Abnormalities felt in this situation require careful examination, for not only do acute but certain chronic conditions manifest themselves here. An important one of these is implantation carcinoma in which cancer cells, detached from a tumor at a higher level in the abdomen, gravitate to the culdesac, there engrafting themselves on the peritoneum and forming an induration described by Blumer as a "rectal shelf." When this is felt by rectum we know that the tumor is secondary and that radical surgery is contraindicated.

Tuberculous peritonitis.—Plastic tuberculous peritonitis may, to palpation, resemble carcinoma of the culdesac, but is to be differentiated by the history, symptoms and other physical signs.

Uterine displacement.—Regarding displacements of the uterus, it seems to me there should never be a doubt as to its position if it cannot be determined by bimanual examination. The uterine sound, introduced aseptically, is a reliable guide to its position, and if the corpus uteri is anterior the tumor felt by rectum is not the fundus of the uterus but may be a tumor of the uterus, as a fibroid, a growth or inflammatory process in the culdesac, or a tumor of the rectum, the latter to be recognized by proctoscopy.

Finally, early recognition of a tumor of the rectum or rectosigmoid is due, not so much to a lack of knowledge, as to failure to apply, at the earliest moment, the knowledge we possess.

SURGICAL PROGNOSIS

In the present state of knowledge of the therapy of intestinal carcinoma, it may be stated as an axiom that removal of the growth by radical surgery is indicated in all operable cases, and irradiation in all inoperable cases. Partial operations in radically inoperable cases are harmful and should not be done. Colostomy is a palliative measure of the highest value in carcinoma of the lower bowel to relieve obstruction, actual or threatened, preparatory to surgical removal of the growth, and as a preliminary to radium therapy. At the same time the operator may ascertain gross evidence of abdominal metastases.

Surgical prognosis concerns itself with operative mortality and recurrence *in loco* or metastatically. Shock, hemorrhage, pneumonia, suppression of urine and infection are the chief causes of operative mortality. To combat these, Crile (1) has adopted, with marked success, the following sound prophylactic measures: 1, Blood transfusion before and after operation; 2, hypodermoclysis to maintain water equilibrium; 3, wrung out iodoform gauze left in situ on all raw surfaces four or five days to prevent contamination becoming infection, and 4, nitrous oxide oxygen analgesia and local anesthesia to minimize interference with the internal respiration of the cells. Evidence of the value of these precautions in combating in anticipation shock, acidosis, toxemia and infection, are forty-five cases in which radical operation was performed in two stages with only one operative death (pneumonia).

Recognizable metastases in the viscera or peritoneum, of course, preclude radical surgery. The borderline of operability has risen in recent years so that involvement of adjacent organs, such as the prostate or uterus, may not always bar radical surgery. Simple infection through the ulcerated tumor may explain enlargement of the regional lymph nodes, so that a patient should not be denied operation because of regional glandular involvement alone. Pennington (2) collected data of 997 necropsies. The regional nodes were involved in 334 or thirty-three per cent.

PATHOLOGY

Hausmann, of Vienna, in a study of 112 cases of carcinoma of the rectum that were examined post-mortem, found the disease localized in the bowel wall in fifty-five. The rectal fascia is the natural barrier to extension beyond the bowel wall proper.

McVey (3) has studied one hundred specimens removed by operation at the Mayo Clinic. The ano-rectal lymph nodes dissected out numbered six + for each specimen. No glandular involvement was shown in fifty-three per cent., slight involvement in thirty per cent., and marked involvement in seventeen per cent. McVey concluded that "the size of the growth cannot be relied on as an accurate index of the probable lymphatic involvement. The growths without lymphatic involvement tend to grow into the lumen of the bowel. Growths with slight lymphatic involvement tend to spread by direct extension and are slow growing. Carcinoma of the rectum, with extensive lymph glandular involvement, tend to metastasize through the lymph stream early. Occasionally metastasis may take place by embolic breaking off into the portal vein. Systematic microscopic examination of all the regional lymph nodes in carcinoma of the rectum appears, as it does in carcinoma of the stomach, to be the best method of ascertaining an accurate prognosis for the case."

On the other hand, Jones and McKittrick (4) reported clinically that although the pathologist found no involvement of the perirectal tissue or glands in sixty-eight per cent. of specimens removed by them at operation, nevertheless all but 11.3 per cent., or less, of the patients seen were dead within five years, whether metastases were found outside the bowel or not. Ninety-two per cent. of their patients dying within three years had involvement of the liver, regional glands or perirectal tissue at the time of operation, yet twenty-three per cent. of those having metastases solely in the regional glands or perirectal tissue lived three or more years.

Miles (5), from a study of recurrences in four series of operated cases, determined three zones of lymphatic spread, viz., downward into the perianal skin, external sphincter and ischiorectal fat; laterally into the fascia propria, levatores ani, retroperitoneal lymph glands, the prostate and base of the bladder and, in females, the vaginal wall, cervix uteri and base of the broad ligament; and upward—the most important and rapid—into the peritoneum of pelvic floor, whole length of the pelvic mesocolon and paracolic lymph nodes. In a word, "all tissues in the lymphatics leading from the primary growth are to be considered invaded territory" and the operation reasonably to assure nonrecurrence must include them in a bloc dissection.

OPERABILITY OF RECTAL CARCINOMA

Although the operability of carcinoma of the rectum has risen in recent years, yet thirty to over fifty per cent. are still inoperable when first seen by the surgeon. In this series of 110 cases the operability was sixty-one per cent.

Location.	Radically Operable.	Inoperable.
Anorectal	6	8
Ampulla	50	26
Rectosigmoid	11	9
Total	67	43

Radical operation was refused in nine operable cases. It is a remarkable psychological fact that the same patient who has refused radical surgery when first advised may return months later, under the urge of symptoms of an advanced process, and request operation. In fifty-one of the sixty-seven operable cases a radical operation was performed, twenty-one by myself and thirty by other surgeons. In the series of thirteen in which I performed perineal (Quenu-Tuttle) extirpation, the only operative death was from pneumonia. Two patients died of intercurrent conditions in five weeks and two years respectively. Recurrence occurred in four cases: three months, ten months, one year, and two years respectively. Six patients, or forty-six per cent., are living, clinically free of the disease, two for one year, two over three years, and two over five years, the longest being six years and nine months. Following palliative colostomy, fifteen patients lived from two to eighteen months.

The posterior operation was practised more commonly a few years ago, but because of recurrences has been replaced largely by the combined abdominoperineal operation of Miles, by which the "zones of lymphatic spread" can be removed more thoroughly. Nevertheless, perineal extirpation is, in my experience, the operation of choice in old, obese, flabby individuals, having a growth situated low. The operative mortality of the posterior operation, gathered from large statistics, is about sixteen per cent.

The ideal operation, from anatomical and functional points of view, is a one stage abdominoperineal extirpation, performing an enteroanastomosis by the Balfour or some other method, or drawing the sigmoid colon through the anus and fixing it there. Constriction at the point of anastomosis is usual but

is amenable to dilatation. From the viewpoint of pathology, present surgical opinion is veering toward a permanent colostomy, to be followed at once or some time later by extirpation of the entire bowel distal to the colostomy and a complete dissection of the pelvis. The latter operation minimizes the chance of recurrence and gives the maximum number of clinical cures at the end of three and five years, but the immediate mortality is increased and the patient is left with an undesirable abdominal anus.

The operative mortality of the combined abdominoperineal operation as reported by a number of surgeons having large series of cases varies from 2.2 to 25 per cent. My own series of eight cases is too small to be of statistical value, but a single case is cited to illustrate the value of proctoscopy and biopsy in diagnosis and an ideal operative result.

Case.—A. R., a woman, aged sixty-two, was referred for inveterate constipation and slight rectal bleeding, attributed to hemorrhoids. Her general health and physical condition were good. No active hemorrhoids were present and digital examination of the rectum was negative. Proctoscopy, however, showed a constricting growth of the rectosigmoid, and biopsy proved it to be adenocarcinoma. On February 3, 1923, through an abdominal incision the rectosigmoid was mobilized and the tumor bearing segment excised well beyond the growth. The portion of rectum remaining was then everted, the sigmoid drawn out through it, and end to end union made by interrupted sutures. This patient is now in excellent condition. She has a formed stool daily without cathartics, her weight is normal and only a linear annular scar marks the site of the rectosigmoidal anastomosis.

CONCLUSIONS

No single type of operation is suitable for every case of carcinoma of the rectum or rectosigmoid. To obtain the best results, the surgeon must be familiar with various types of operation and use the method best suited to the individual case, but always observing the imperative rule that no operation can promise reasonable hope of success unless it removes, *en bloc,* the tumor and the regional tissues receiving its lymphatic drainage, and a wide margin of apparently healthy tissue.

Although the results obtained are far from ideal, I feel that they are sufficiently encouraging to stimulate our efforts toward earlier diagnosis, toward the employment of prophylactic measures to reduce operative mortality, toward improvement of technic to prevent the operative dissemination of cancer cells, toward better anesthesia, and to justify, in general, an optimistic attitude toward radical surgery in operable carcinoma of the rectum and rectosigmoid.

Portal Cirrhosis from a Gastroenterological Viewpoint*

ANTHONY BASSLER, M.D.

New York

The study of autolysis and atrophy (1) proves that the liver is particularly prone to intoxication and atrophic changes. The autolysis due to phosphorus, phosgene and mustard gas in which oxygen causes intense acid production with destruction of the hepatic cells is well known. Chloroform causes a more or less profound atrophy of the liver, depending upon the length of exposure due to the breaking up of chloroform in the liver cells through phosgene to hydrochloric acid. Graham has shown that other halogen-compounds similar to chloroform produce like results. Uranium salts produce atrophic changes in the liver. The liver is sensitive to injury by toxins of bacterial origin (2, 3, 4, 5). Thus the injection of hemagglutinins, tetanus and diphtheria toxins, streptococci and their decomposition products, have been found to injure the liver and lead to necrotic changes suggestive of some clinical conditions such as the liver in eclampsia or acute yellow atrophy.

Any medical student who graduated in medicine from a school connected with a large municipal hospital has had ample opportunity to observe cases of portal cirrhosis and examine the pathology of such livers. Chronic alcoholism had been rife for many years, constantly recruiting hospital attendance to such an extent that the etiological connection between this habit and disorders of the liver was recognized. Beginning about twenty-five years ago and continuing up to the broad establishment of abdominal surgery (about ten years ago) the importance of alcohol in this connection continued. Still there were several factors that might have received deeper attention even before ten or fifteen years ago, the most important being that if alcohol as such was responsible for the liver disorder why was it that the condition was more prevalent in those who drank heavily of the malt and fermented fluids (such as beer and ale) as compared with moderate drinkers of spirituous or distilled liquors (like whiskey and gin)? Another question difficult to answer is, Why did one individual acquire the condition from perhaps moderate drinking, and under the same conditions another had no clinical manifestation of it when the second had drunk longer and more heavily than the first? Nevertheless, the one cardinal fact always existed, namely, that heavy and chronic drinking of alcoholic liquors ran rather uniformly throughout all

*Read before the New York Gastroenterological Society, Nov. 24, 1922; Medical Society, County of Queens, Nov. 28, 1922; West End Medical Society, Jan. 27, 1923; Brooklyn Pathological Society, Feb. 8, 1923; Practitioners Club, Yonkers, Feb. 14, 1923.

the cases that were seen, and it was the findings obtained in the operating room when an examination of the liver was made during laparatomies that began to throw some additional light on portal cirrhosis in an etiological way and also proved that this condition of the liver was far more common than it was believed to be.

In 321 laparotomies performed in my practice in 1914 there were 39 instances of definite cirrhotic changes in the liver. Up to the end of 1921 there have been 2,567 laparotomies with records of findings in which terms like "cirrhosis of the liver, cirrhotic liver, hepatic fibrosis, and hobnail liver occur 221 times, or roughly in about eight per cent. In these 221 people distinct chronic alcoholism was present in none. Moderate social drinking of varying grades but all within reason was present in seventy-two men and thirty-eight women. Those who took alcoholic drinks not oftener than once a week at any time in their lives represented thirty-seven men and fourteen women. We then had left sixty people—twenty-nine men and thirty-one women—who had never drunk anything alcoholic and who, nevertheless, had macroscopic cirrhosis of the liver. This brings up three questions. What actually causes cirrhosis of the liver in nondrinkers? In drinkers (accepting alcohol as a factor) is it direct or indirect? Is there a symptomatology of these moderate grades of cirrhosis in which hematemesis, ascites and the classical end symptoms apparently do not occur?

Portal cirrhosis is supposed to occur most frequently in the fifth decade of life and judging from the time of the distinct symptoms of the condition this is correct, yet the average age of my patients was thirty-eight years. In Osler's *Modern Medicine* (6) the following occurs: "There is reason to believe that poisons, particularly the fatty acids (lactic, butyric, acetic, valerianic, etc.) and other ill understood enterogenic toxins associated with different forms of indigestion, may be the causative factors, especially in nonalcoholic subjects who give a history of long continued indigestion, following or associated with overindulgence in seasoned foods, spices, etc. (dyspeptic cirrhosis, Budd's nonalcoholic cirrhosis). The fatty acids and other toxins rarely may be ingested preformed with the food; but they are more to be manufactured in the intestinal tract in cases of gastrointestinal catarrh (fermentative dyspepsia); experimentally lesions resembling those of cirrhosis have been induced by injecting fatty acids into lower animals. To the influence of enterogenic toxins, spices, etc., may also be attributed the cirrhosis occurring among the Hindus, Egyptians, and other races, who, avoiding alcohol, nevertheless often eat food that is not above reproach and are quite partial to condiments and spices, such as ginger and pepper, often in decoctions."

In the saccharobutyric type of chronic intestinal toxemia the condition is due to the large numbers of strict anaerobes having their location mainly in the colon and lower ileum. The chemistry in these types of infections is definitely acid in contradistinction to the alkaline found in putrefactive conditions. Without burdening you with a detailed presentation of the bacteriology characterizing this type of toxemia, it serves our purpose here to say that the Bacillus coli content is always low or negligible in a restrictive sense. The organisms present are capable of attacking the carbohydrates and proteins in a vigorous manner with the formation of butyric, indolamido, propionic, caproic, valeric, lactic, oxalic and indolacetic acids. The stools are usually acid in reaction although this may have been neutralized by bases formed in the process of putrefaction, and especially by ammonia and ammonium butyrate. That there are other products in this type of infection is proved by the large marsh gas formations from the Bacillus putrificus which is as distinctive as the acidity from the Bacillus aerogenes capsulatus and the gram positive cocci. There may also be bacterial toxic substances for these from the Welch and the Bacillus putrificus is easily proved. Practically all these products are volatile or readily soluble and it is reasonable to assume that this resorption into the portal system occurs where their production is excessive in the intestine.

My interest in this connection began in 1914 when at operation for cholelithiasis on a young Quaker woman who had never drunk anything alcoholic in her life, a marked hobnailed liver was disclosed. This woman since then died after repeated tappings from hematemesis. She had a marked saccharobutyric toxemia for which no special treatment had been carried out. Beginning early in 1915 practically every case was studied and I have yet to see one instance where, at operation, whether the individual were alcoholic or not and a portal cirrhosis was disclosed, there was not present and easily demonstrable a saccharobutyric toxemia in the intestinal canal. My operative records are now most complete in 194 of such cases, and from them it seems logical to assume that the etiological connection between this type of intestinal toxemia and portal cirrhosis is of more than passing interest, especially in view of the fact that saccharobutyric toxemia is such a common condition and moderate enlargement and increase of firmness of the liver are so often met with in abdominal examinations. In this type of toxemia, drinking of alcohol and fermented malt fluids, feeds the infection present and enhances it.

It is an old teaching in medicine that where the spleen is palpable in the abdomen it is enlarged. It is just as accurate to take as a clinical dictum that when the liver is distinctly palpable in the abdomen, either the left lobe alone or the lower part of the entire organ is enlarged. Ordinarily, the liver is not palpable, there being elicited only a vague and indefinite sense of fullness in the epigastrium. Usually the right lobe is entirely above the confines of the lower margin of the costal margin and ribs. The left lobe sweeps across the abdomen in the epigastric region, and here that indefinite sense of resistance may be best noted. Under normal conditions the edge is never palpable. When the liver is enlarged its increase in bulk more completely fills the lateral dimensions, which is not demonstrable. What may be noted is its increase of bulk causing a lengthening of its vertical diameter. This drives the lower edge downward and below the costal margin on the right and deeper into the abdomen in the midline. In all abnormal states of the liver there is an increase in

firmness of the organ, so much so that at times the convex anterior portion of the left lobe is easily palpable and the more often a real pathological condition is present the more definite the palpability of the edge. The liver hugs the under surface of the right diaphragm rather closely and the percussion of this concave surface, with the distinct change in the percussion note as we come down from the thorax to the abdomen, is distinct and marked. Ordinarily this corresponds at its highest point on the right to the same interspace as the heart apex on the left, namely the fifth. Under all conditions the percussion should cease at noting this upper margin of the organ, because it is a fact that its percussion in the abdomen is too open to error and it is far better examined by light palpation. This is easily possible in obese persons. Upon liver examination it is surprising how many instances of moderate degrees of enlargement of the organ are met with in clinical practice. One rarely hears or reads any statements of the size and firmness of the liver and yet I am meeting with it daily. If attention is paid to this item in physical examination and clinical reports are checked up with the findings at operation and postmortem, the significance is at once apparent.

The records of cases of saccharobutyric toxemia show that enlargement of the liver is frequently present. Usually this is manifest in an enlargement of the whole organ, so that the lower part of the right lobe is lower than normal, although this may not be palpable on the right of the mammary line and in the flank. It is most easily felt in the left lobe which not uncommonly is distinctly firmer than normal, the convex surface can be made out, although palpability of the liver edge is uncommon—in fact, rare. The deduction as to whether a pathological condition is present in the organ or not is not always easy, mainly because in younger persons gallbladder disease (usually cholelithiasis) often is present in this type of toxemia and in cholelithiasis enlargements and increased firmness of the left lobe of the liver are commonly found. In older subjects distinct changes in the heart, vessels and kidneys may exist and more or less enlargement of the liver be present in disorders of these organs. When, however, these disorders can be eliminated, as well as other conditions in which liver enlargements may be found, and especially when the liver enlargement is practically permanent after the toxemia has had attention, more or less cirrhotic change in the liver should be assumed. When a distinct portal fibrosis has occurred, a complete reduction in the size of the liver is difficult to bring about and such benefits as result occur slowly and require a considerable length of time. I have observed cases in which a rapid reduction in the size of the liver was quickly brought about, but in these patients I have believed that only congestive and not fibroid deposit was responsible for the enlargement.

A critical study of the symptomatology of portal cirrhosis before hemorrhages and ascites in a considerable number of cases leaves practically nothing definite to describe. An analysis of the symptoms which are present before these end results occur in the definite alcoholic cases shows that for often a year or two there has been distress in the stomach region, more or less independent of meals, but usually intensified by excess quantity. In a large proportion of cases, however, there are no symptoms at all before the hemorrhages or the ascites occur. Then there are other cases where the cirrhosis of the liver may remain latent for years. It is probable that when symptoms occur early in the disease they are caused by an ill defined active congestion of the organ. Occasionally there is a sense of weight in the right hypochondrium, perhaps short transitory attacks of slight fever, a mild jaundice of a few days' duration, and sometimes a sense of pain and discomfort in the liver region. When such are present tenderness on deep pressure over the liver may be elicited. In many more cases the early symptoms are those that cannot be dissociated from a gastroenteric catarrh or the saccharobutyric toxemia. Among these can be enumerated coated tongue, flatulence, irregular appetite, nausea and sometimes vomiting in the early morning, alternating constipation and diarrhea, hemorrhoids, and similar diseases. The functional capacity of the stomach and intestines may be diminished, the gastric and intestinal juices being affected by the catarrh. There may be loss of weight due to diminished resorption power of the intestines, often inhibiting peristalsis. Tympanitic attacks may occur. The symptoms that more particularly are the result of the intestinal toxemia are fatigue, anorexia, insomnia, irritative skin lesions, asthenia, substernal distress, and those that centre around the diagnoses of gastric atony with hypersecretion, ileal stasis, chronic colitis and gallbladder conditions. I need not say anything about the late symptoms due to portal blocking, all of which are well known to you.

In the average case that is referred to a gastroenterologist, where there is enlargement of the liver and the laboratory suggests the presence of a saccharobutyric toxemia, whether the subject be alcoholic or not, a degree of cirrhosis of the liver should be suspected when no other cause for liver enlargement exists. A reasonably rapid reduction in the size of the liver is not accomplished on treatment—say in four weeks' time. I believe with Foxwell that whatever the stage of the cirrhosis, enlargement of the liver always occurs, and in the grade of cirrhoses cases I am undertaking to describe small livers are never seen. Quite naturally since the size of the liver is the main presenting symptom leading to suggestion of the condition one must exclude other causes of enlargement of the liver such as passive congestion, fatty liver, malaria, syphilis, and malignant disease. Viewing it from another angle, when a diagnosis of saccharobutyric toxemia in the intestine is warranted, the presence of an enlarged liver that can not be accounted for from some other cause should warrant the diagnosis of cirrhosis.

Unfortunately the term cirrhosis of the liver has a limited association in the average medical man's mind and is entirely encompassed in the picture seen in the late stages of a lethal case. On hearing it he promptly thinks of an old alcoholic with hematemesis, ascites, enlarged veins, etc., and not seeing these in the case before him criticizes the diagnosis. He fails to remember that in these extreme cases the disease existed for years before these end symptoms occurred, and that while the diagnosis of cirrhosis of the liver in the earlier stages may have been a

difficult and inconclusive matter for him, it could and should be made far more frequently than is being done. If he pays more detailed attention to the examination of the size and consistency of this organ in his dyspepsia cases, and especially if he observes the operations on some of these patients at which the liver surfaces are examined, the diagnosis would not be so easily and definitely dissipated by him. There are many of these patients who growl with dyspeptic symptoms and those due to deficient general health for years without a proper diagnosis having been made showing the characteristic end symptoms of portal cirrhosis. There are not a few gastroenterologists, too, in whom this diagnosis strikes the same unfair conclusion and is practically never made. And added to this gentle and kindly criticism may I add that of the patient with whom the term cirrhosis of the liver strikes an absurd note; with him or her it is better to use the phrase "hardening of the liver."

An Instrument for the Treatment of Peritonitis and for Intraabdominal Manipulations

CHARLES L. LARKIN, M.D.

Waterbury, Conn.

Assistant Gynecologist to the Waterbury Hospital

The study of peritonitis and the great need for more efficient methods in the treatment of this devastating disease have led me, within the last two years, to devise an instrument which I have called an abdominal caisson. Experimentation upon the human cadaver and the living dog warrants the presentation of this instrument to the profession for further animal experimentation and for actual use upon the human body. Besides its proposed use in the treatment of peritonitis, this instrument is adapted for any intraabdominal manipulations which demand a ready entrance and egress to the individual cavity over a period of days, or even weeks, such as the treatment of a malignant growth of any of the abdominal organs by radium.

The caisson can be made in any number of sizes. I have made them in but three, and the accompanying photographs and descriptions are of the middle and small sizes. It is shaped like a silk hat without a top, as shown in Fig. 1. It has a brim or flange one inch wide and an upright wall of six inches. The cavity is elliptical in form measuring five inches anteriorly posteriorly and two inches in its widest dimensions. At the juncture of the flange and the upright wall are placed a number of steel eyelets one half inch apart and running entirely around the caisson. An inch and a half from the top is placed a small metal tube which pierces the side wall, one half inch of tubing appearing on the outside surface and one half inch on the inner side. Running entirely around the middle of the wall of the caisson is a rubber beading.

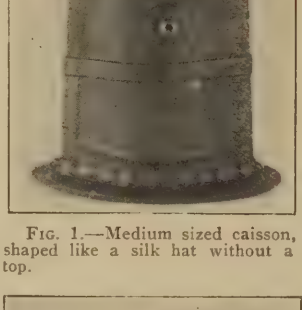

Fig. 1.—Medium sized caisson, shaped like a silk hat without a top.

Fig. 2.—Caisson held in place in abdominal cavity by mattress sutures.

To place this part of the apparatus in position it is necesssary to make a midline incision in the abdomen beginning about three and a half inches above the umbilicus and extending an equal distance below. The caisson, flange first, is then slipped into the abdominal cavity and held in place by nonabsorbable sutures. These sutures are passed, as shown in Figs. 2 and 3, as mattress sutures, beginning about one half inch from the skin edge through the whole thickness of the abdominal wall, taking a slightly oblique course so that they pass through the peritoneum at about one quarter inch from the cut edge, then through the eyelet of the caisson and back again through the peritoneum and abdominal wall leaving one quarter inch of the tissue between the strands. These sutures can be placed so that the skin and abdominal layers will fit snugly to the upper surface of the flange and to the lower caisson wall. The sutures may be tied over very small rubber tubing, as shown in Fig. 4, or without intervening material. This makes a water tight union, but to allow for later shrinkage of the abdominal wall away from the caisson and to protect the cut surfaces from the air, the abdomen is smeared with boric acid ointment and a rubber dam and collar are fitted over the caisson. The collar fits snugly over the lower caisson wall and the dam spreads out over the abdomen and with the help of the ointment it adheres closely. To keep the dam in position and to make

a uniform pressure a metal collar, elliptical in form, is used. This collar in turn is kept in place by braces that extend from another collar that fits under the rubber bead that is part of the caisson wall. The braces connecting the two metal collars are threaded and fitted with thumb nuts so that the distance be-

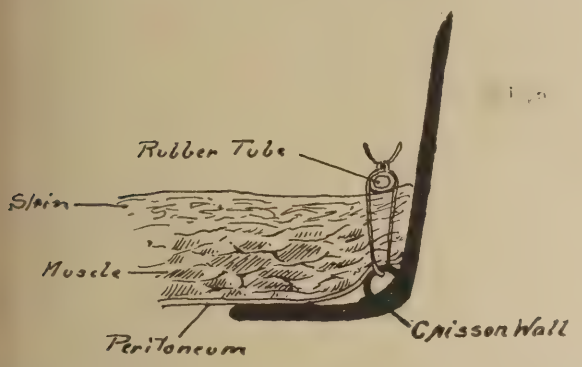

Fig. 3.—Mattress sutures beginning about half an inch from the skin edge, to hold caisson in place.

tween the collars can be easily adjusted to different thicknesses of the abdominal wall. These metal collars can be placed in position by simply removing one pin.

The top or cover is made of solid brass, recessed on its under surface, and contains a thin sheeting of rubber tissue. Piercing the top are three small brass tubes, one half inch of tubing appearing above and one half inch below the cover. In the centre of the cover is a hook. Soft pliable rubber tubes are inserted into the abdominal cavity, one in either kidney fossa and one in the pelvis and then connected with the brass tubes on the under surface of the cover. Another piece of rubber tubing is placed in the pelvis and connected with the brass tube in the side wall.

When the caisson, the rubber dam, metal collars and the cover are in place, the cover is held firmly by two arms that swing from the upper metal collar and fit into a notch at either end of the cover. The arms are threaded and the thumb nuts can be screwed down making the top absolutely tight. Rubber tubes are connected with the three inlet tubes in the top. These tubes in turn are connected with a Carrel irrigating glass tube and this in turn with a single tube that comes from a glass container which holds the irrigating solution. Another rubber tube, attached to the brass tube on the outside wall, leads to a basin beneath the bed, thus forming a complete syphon drainage. A cord has been fastened to the hook in the top and leads upward through two pulleys fastened to framework directly above the bed and the distal end suspends a proper weight for removing the pressure of the caisson from the abdominal wall and at the same time increasing the abdominal cavity.

Fig. 4.—Showing sutures tied over small rubber tubing.

Fig. 5 is a schematic representation of the caisson in position. The abdominal cavity is increased in size corresponding to the size of the caisson used. The ballooned up intestines that have been closely packed together are released from their cramped quarters and corresponding to the amount of distention will partly or more fully fill the caisson. The intraabdominal pressure is lessened and the absorption of the bacteria and toxins proportionately decreased. The interspaces between the loops of intestines are larger and the friction between the inflamed serosa surfaces is lessened and there is better drainage between the loops of the intestines and from the upper abdominal region to the pelvis.

The whole abdominal cavity can be thoroughly

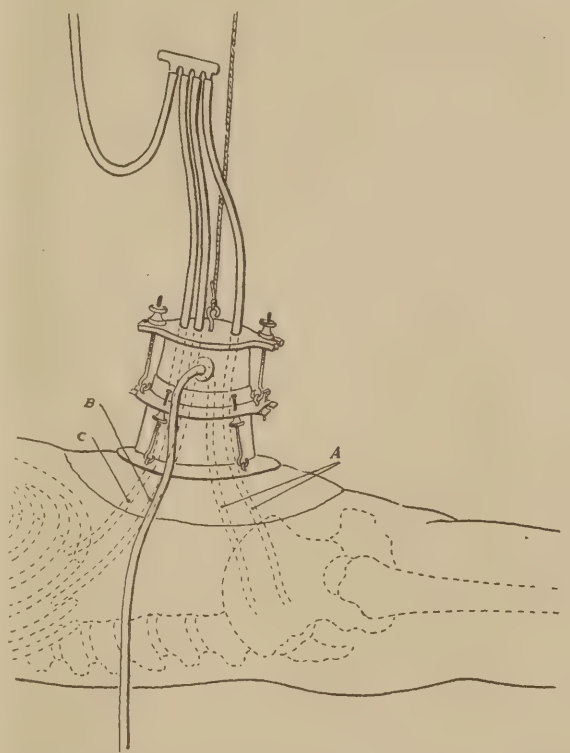

Fig. 5.—Schematic representation of caisson in position. A, leading to Douglas's pouch; B, right kidney fossa; C, left kidney fossa.

washed out at will, and the fluid and infected material carried off again by the syphon drainage tube. If at any time there is cause to believe that the drainage is not complete it is an easy matter to lift up the cover and inspect the abdominal cavity. With the larger sized caisson the surgeon may insert his hand into the abdominal cavity and perform any manipulation desired. With a smaller caisson only instrumental manipulation can be performed, such as replacing the rubber tubes in their proper places by means of sponge holders; or adhesions may be separated or walled off foci broken into and drained. When the infection has been arrested the caisson can be removed and the abdomen closed tightly as in any intraabdominal operation.

This method of treatment is recommended in those advanced cases of acute diffuse peritonitis where the

patient shows a clammy blue skin, rapid thready pulse, low or subnormal temperature, with great abdominal distention and rigid abdominal wall, with a low white count and where the surgeon has been accustomed to say that nothing can be done.

The smallest caisson is a miniature of the larger sizes, its cavity measuring two inches anteriorly posteriorly and one inch in its widest part. The flange is three eighths of an inch wide and the upright wall is two and one half inches high. It is inserted in the same manner, but it does not have the metal supports. The cover is made of hard rubber and fits snugly onto the caisson.

This caisson is devised for use in localized peritonitis, in tuberculosis of the cecum, in fecal fistulæ, in the treatment of malignant intraabdominal growths, etc. It keeps the abdominal cavity open. It does not impinge upon the intestinal walls. It allows direct treatment of the focus of infection.

99 North Main Street.

Food and Health

ROBERT HUGH ROSE, M.D.,
New York

Why not eat right and be well? Much sickness is due to wrong eating. Vigorous health is impossible without proper food. Since selfpreservation is the first law of nature, knowledge of the constituents of a correct dietary should be the first interest in life. It is important to everyone and especially so to the physician whose duty it is to ferret out this knowledge and give it to the world. The energy which the body uses, as well as the body tissues themselves, can be obtained only from the food eaten. Your food must contain all these necessary constituents in sufficient amount. It may be injurious to have a great excess of certain constituents, as for instance proteins, but it is much worse to have a deficiency. It is not so easy to determine what a proper diet is. The fact that vitamines, which have been known only for a few years, are essential to health indicates that our knowledge is not yet complete. We must not only have the proteins, carbohydrates and fats in fair proportion and sufficient amount, but we must also have the minerals and vitamines as well.

PROTEIN

The proteins are tissue builders. I will not enter at length into the discussion of the required amount but will simply say that seventy grams daily is a golden mean and I will tell how to obtain that amount. We may later conclude that fifty grams or less is more nearly ideal, but I wish to be conservative and I do not think that, with the seventy grams daily (if this is a slight excess), the extra work placed thereby upon the kidneys in the elimination of its byproducts would be enough to be injurious to them. I will give a list of ten of our chief sources of protein and show how much we may obtain from a certain quantity of each of them. In the fall of 1915 I showed in an article which appeared in the New York Medical Journal that we obtain unintentionally considerable quantities of protein, that is, that we get it from foods classed not as proteins but as carbohydrates and, to a less extent, as fats. This amounts in an average mixed diet to almost one half of the protein requirement. A good example is bread, which is fifty per cent. carbohydrate, but if six thick slices are eaten in a day, it furnishes about fourteen grams of protein, or one fifth of the day's requirement.

Since, as I have just stated, foods not classed as protein furnish us almost one half of the day's protein requirement, we can easily calculate the amount of protein foods we need, figuring to obtain between thirty-five and forty grams daily from them. Three tenths of a pound of meat satisfies this requirement. If for any reason the patient is taken off a meat diet but milk is allowed, a quart of milk furnishes practically the same amount of protein as three tenths of a pound of meat. From milk and eggs, therefore, it is easy to obtain all the protein necessary without touching meat. Strict vegetarians may not always take enough protein but there is no reason why they should not easily obtain at least as much as the Chittenden standard, that is, fifty grams a day. They generally eat whole wheat bread, beans, peas, figs, dates and nuts. In a heaping tablespoonful of almonds there are five grams of protein. In a medium sized saucer full of figs, dates or raisins there are two and one half grams of protein. A banana weighing three and a half ounces contains one and a half grams protein. When meats are not eaten it must be remembered that helpings of vegetables are naturally much larger. Four heaping tablespoonfuls of peas furnish ten grams of protein. Just as a suggestion I call attention to the fact that two heaping tablespoonfuls of shelled almonds, four heaping tablespoonfuls of peas and two slices of bread half an inch thick give twenty-four grams of protein or one half the Chittenden standard. This could easily be eaten at one meal and as you will see there would be no difficulty in satisfying protein requirement in the three meals if the food of the vegetarian were properly selected, even though he excluded milk, cheese and eggs.

CARBOHYDRATES

The carbohydrates are conveniently divided into two classes, the high content carbohydrates and the low content carbohydrates. The former comprise grain products, such as cereals, breadstuffs, macaroni and potatoes, both sweet and Irish. In addition there is sugar in its various forms, including honey. These concentrated carbohydrates are necessarily

part of one's diet, although they have been greatly abused. From the viewpoint of health, too, much sugar and sweets have been consumed. The increased incidence of diabetes is partly, at least, due to a great increase in the use of sugar. These products have also been too much refined, but of that I shall speak later. Another objection is to their use in the form of desserts. Too great a concentration of foods is a mistake. In a measure it does away with the necessity of chewing and it must be remembered that carbohydrates are digested by saliva. It also permits the ingestion of too much nourishing food and is one of the causes of obesity on one hand, with its train of ills, and gastrointestinal fermentation on the other with its ills. In the average diet of a person of sedentary habits, such as most city dwellers, high content carbohydrates furnish one thousand calories. The low content carbohydrates, including coarse vegetables, fruits and greens, furnish three hundred to four hundred calories. Taken together the two classes of carbohydrates furnish six tenths of the day's food. If one has a tendency to lose weight, the high content carbohydrates with the fats should be used in more than average quantity. If, on the other hand, there is a tendency to gain weight, the low content carbohydrates should be used in larger proportions.

FATS

The fats comprise butter, olive oil, egg yolk, bacon and fat cuts of meat. In addition to furnishing fat soluble vitamines, which recent experiments show are an important factor in health, they supply between two and three tenths of the day's calories. There are countries where fats form a much higher portion of the day's menu, such, for example, as the countries of the Esquimos.

VITAMINES

Since it is now recognized that vitamines are of great importance, we can no longer think of properly choosing our food without taking them into consideration. The investigation of the subject is so recent that our knowledge is far from complete, but we at least know how to play safe. We know that by eating fruits and vegetables, including green leaves, we obtain all the vitamines. We know also that butter and cream contain more fat soluble vitamines than vegetable oils. We know that fat soluble vitamine A is essential to growth and for the full grown it is essential to health. We know that it has the power to increase the resistance against infectious diseases. We know that vitamines B and C are also essential to health, that without vitamine C scurvy develops and without vitamine B poor appetite, mild symptoms of poor health and eventually a disease of the nervous system called beriberi. Articles which contain all the vitamines are tomatoes, fresh cabbage, carrots, cauliflower, lettuce, spinach and whole milk —though the vitamine C in milk is rather easily destroyed by heating and is somewhat dependent upon the greens in the diet of the cow and therefore is less in late winter and spring than in other seasons. Oranges and tomatoes have perhaps the best reputation at present for the vitamine C content. Vitamines have a marked influence on the teeth and gums in addition to the effects already mentioned.

MINERALS

While it has been customary to state that minerals are an important part of the diet there is little of a definite nature in medical literature on this subject. The work of Sherman on calcium indicates that the diet of the American people is more likely to be lacking in lime than in protein. The body of a man weighing 154 pounds contains approximately four and a half pounds of calcium oxide (lime). The day's requirement of lime is fifteen grains. I have shown in the accompanying chart the important sources of lime. It seems apparent that without milk or cheese in one's dietary, it is not easy to obtain enough lime. The only possibility is to select fruits and green vegetables and use generous helpings of them. It is quite easy, however, to obtain the day's supply when cheese and milk are included in the menu. Two and a half glasses of milk furnish the entire requirement for the day. One glass, therefore, furnishes two fifths of the requirement. With one glass of milk and a good helping of cheese daily there would not be the slightest danger of being undernourished in calcium. The bones and teeth, much alike in composition, are about eighty-five per cent. calcium phosphate and ten to twelve per cent. calcium carbonate. Is it not suggestive, since in this country we are not taking our proper allowance of lime, that the almost universal presence of cavities in the teeth may be due to this fact? We know of races in the past who did not use any special measures for preserving the teeth, such as we use today, who were practically free from tooth troubles. It may not be so much the sugars we eat, which have often been blamed, but the lime, which we do not eat, that is the cause of this abnormal condition.

IMPORTANT SOURCES OF PROTEIN

DAILY PROTEIN REQUIREMENT IS 70 GRAMS = 2½ OZ. = 287 CALORIES = ½ GRAM OR 2 CALORIES A POUND OF BODY WEIGHT.

	Grams
Meat, 5 oz.	= 34.5
Milk, 1 quart	= 33.0
Cheese, cream, 1 oz.	= 8.0
Cheese, American, 1 oz.	= 8.0
Bread, whole wheat, 6 oz.	= 17.4
Eggs, 2	= 13.0
Baked beans, 2.6 oz.	= 5.4
Peas, 2 tablespoonfuls	= 5.0
Cereal, moist, 1 helping	= 3.0
Banana, 3½ oz.	= 1.5
Orange, 4 oz.	= 1.0

IMPORTANT SOURCES OF LIME

DAILY REQUIREMENTS 15 GRAINS CaO.

	Grains	Requirement
Milk, 10 oz.	= 7.3	= 1/2
Cheese, 1 oz.	= 5.7	= 1/2.5
Mustard greens, 2 oz.	= 6.0	= 1/2.5
Turnip tops, 2 oz.	= 4.2	= 1/4
Molasses, 2 oz.	= 2.5	= 1/6
Bread, Boston brown, 3 oz.	= 2.37	= 1/7
Oranges, 7 oz.	= 1.9	= 1/8
String beans, 4 oz.	= 1.2	= 1/13
Spinach, 2 oz.	= 0.8	= 1/19
Bread, whole wheat, 6 oz.	= 0.79	= 1/19

IMPORTANT SOURCES OF IRON

DAILY REQUIREMENTS 0.2 GRAINS

	Grains	Requirement
Romaine, 2 oz.	= 0.1	= 1/2
Eggs, 2	= 0.048	= 1/4
Bread, graham, 6 oz.	= 0.06	= 1/3
Bread, whole wheat, 6 oz.	= 0.042	= 1/5
Beef, 6 oz.	= 0.055	= 1/4
Mustard greens, 3 oz.	= 0.063	= 1/3
Spinach, 3 oz.	= 0.045	= 1/5
Chard, 3 oz.	= 0.03	= 1/6
Dandelion greens, 3 oz.	= 0.03	= 1/6
Prunes, 2 oz.	= 0.026	= 1/8
Raisins, 1 oz.	= 0.009	= 1/20

PHOSPHORUS

The amount of phosphorus in the body is more than three pounds. Thirty grains of phosphorus pentoxide is the approximate daily requirement. Since phosphorus is commonly associated with protein food, and since the American diet is high in protein, there is not much danger of our getting too little phosphorus. It is present in meat and eggs as well as milk.

IRON

The amount of iron found in the human body is, on an average, one tenth of an ounce; it is estimated that two tenths of a grain covers the average daily requirement. The American dietary is not likely to be low in iron but there are many cases in which this does obtain. It is present in meat but it is not present to any considerable extent in milk or cheese. White sugar and white flour have had most of the iron extracted. This makes it possible for a person to eat a diet of white bread, cake, pastry with milk and cheese, not much meat, plenty of fat and be overnourished, as far as adipose tissue is concerned, but anemic. There is a great difference in the amount of iron contained in various articles of food. Generally speaking the green leaves contain the largest amounts but romaine is the richest of all. From two ounces of romaine one can obtain one half of the day's requirement. A good helping of spinach furnishes one fourth of the day's requirement. A helping of oatmeal furnishes one twelfth of the day's requirement. Three slices of whole wheat bread furnish one eleventh of the day's requirement. It would take six quarts of milk to furnish the requirement of iron if milk were the only food.

FOOD AND HEALTH

The accompanying menu for a day will serve to illustrate how the various requisites of one's dietary may be obtained. It was drawn particularly to show how to obtain the necessary proteins and minerals and was presented before the New York Stomatological Society. It furnishes 2,325 calories which is quite sufficient for the average person living in the city. Seventy-five grams of protein are included. This is a conservative up to date estimate for protein.

Over twenty-two grains of lime are furnished in this menu. This includes a helping of cream cheese. The latter could be omitted and still leave an abundance of lime. It will be noticed that it is obtained largely from ten ounces of milk. The chart which shows the important sources of lime would indicate the possibility of obtaining lime from greens. Mustard greens, if five ounces were taken in a day, would furnish the entire requirement. Five ounces of turnip tops would furnish ten grains, or two thirds of the requirement. Thus, it may be seen that by consulting a list showing the calcium content of articles of food the requirement can be obtained from eating regularly generous helpings of greens.

The amount of iron furnished in this day's menu is 0.36 grains, more than fifty-two per cent. in excess of requirement. By consulting the table giving important sources of iron the value of greens for this purpose is seen. Three ounces of mustard greens furnish one third of the day's requirement. Six ounces would be a generous helping of mustard greens and this would supply two thirds of the requirement. From the bread, meat, eggs, potato and oatmeal in this menu 0.0180 grains are obtained. The eggs and beef furnish 0.13 grains or two thirds of this. From the tables it can be readily seen that it is entirely unnecessary, if one has the information on the subject, to permit the diet to be inadequate in any of the essentials discussed. It is particularly important to have the proteins, calcium, phosphorus and vitamines in order to insure the proper development of the teeth and to prevent caries. As some of the experiments have indicated, the teeth are an excellent indication in many cases of the correctness of one's diet, as they often show its inadequacy when there are practically no other symptoms of disease present.

Hereditary Immunity to Rhus Dermatitis

JAMES B. McNAIR, M.D.
Chicago

Considerable emphasis has recently been laid upon what may be acquired immunity to Rhus dermatitis but very little attention has been given to natural immunity to this disease. Animal experiments have not been successful in Rhus dermatitis since the skin of most of them is apparently immune to the action of Rhus poison. So for the present at least, analysis of data is necessarily confined to human statistics.

As I have stated elsewhere (1) it is doubtful if absolute natural immunity exists toward this disease. Persons are frequently found who are immune to the poison when it is applied in the same concentration and condition as it exists in the sap of the plant, but when applied in a more concentrated form these persons are affected by it. Von Adeling, in 1912, found that the concentrated alcoholic extract of poison oak (Rhus diversiloba T. and G.) affected every immune person to whom it had been applied. Similar results were obtained by Warren in 1909, with poison ivy (Rhus toxicodendron L.). Brown (1922), in experimenting on nine individuals with an alcoholic poison ivy extract of unknown strength, found three immune.

Spain (1922), in experimenting on eighty individuals, all but one of whom were over eight years old, with an ethyl alcoholic poison ivy extract of unknown strength, found fifty-two or sixty-five per cent. susceptible. Bibb, in 1914 and 1915, however, in experimenting with the sap of Rhus toxicodendron, found a person on whom it had no deleterious effect.

Earlier immune results with the sap of Rhus toxicodendron were noted by Kalm, in 1748, by Van Mons, in 1797, and Blackwood in 1880. I have observed similar cases with Rhus diversiloba. The sap of both the poison ivy and the poison oak has frequently been observed to have been transmitted from the hands and clothing of immune gardeners and those who have been working with the plants to others who were susceptible to it (Planchon, 1887; Busey, 1873; White, 1873; Lindley, 1908). Similar examples of relative immunity are found in experiments with bacteria and toxins on animals; for instance, rats are highly immune to diphtheria toxin, and readily withstand the effects of an amount equaling one thousand lethal doses for a guineapig, but still larger doses may prove fatal; hedgehogs possess complete or almost complete immunity for the amount of snake venom deposited in an ordinary strike, but if the venoms of several snakes are collected and injected at one time, death will result.

Although it is doubtful if absolute immunity does occur yet it is thought that natural relative immunity exists toward this disease because of the comparatively small number of persons highly susceptible to skin poisoning from Rhus poison. Among 28,756 university students, 1,602, or 5.57 per cent., were treated for Rhus dermatitis. Of these 855, or 2.97 per cent., were males, and 747, or 2.59 per cent., were females (1). That is, approximately one person in eighteen is highly susceptible and about the same number of males as females are poisoned.

From the cases which I have studied a definite and marked susceptibility to Rhus dermatitis exists in certain families and family generations. This family tendency is usually more pronounced when there is a history of dermatitis in the paternal and maternal lines.

It is not unnatural for hereditary tendencies to skin diseases to occur in man. Undeniable occurrence of skin conditions is seen in benign tumors and especially various cutaneous growths that are essentially benign neoplasms. Several records of dermatological heredity of these have been collected by Meirowsky and Bruck (2). Hereditary telangiectasis is also well known. The literature on this was reviewed by Goldstein (3). Multiple benign cystic epithelioma is one of the growths that has a distinctly familial distribution and these growths (4) which usually resemble carcinoma histologically sometimes become malignant.

To illustrate the hereditary character of these cutaneous growths the following case reported by Heidingsfeld (5) may be cited, of a man sixty-five years of age, with four children all of whom, himself included, exhibited a growth on the nose. His maternal uncle and aunt had similar growths, his mother died at thirty without having any growths, and there had been no cases on the paternal side.

Assuming that hereditary immunity to Rhus der-

matitis exists, it may occur in accordance with the Mendelian principles, for the following reasons:

1. The principles of inheritance worked out by Mendel with garden peas have so far been found to hold good for all multicellular living things, whether plants or animals.

2. Mendelian principles do appear in human inheritance. For example, in hereditary hemophilia and in color blindness perfect illustrations are found of an inherited sexlinked recessive character. Eugene Fischer (6) reports that in the crossing of Europeans with Hottentots, transmission of characters occurs in accordance with Mendelian expectations. Another illustration of human heredity conforming to the Mendelian principles is seen in the separation of human red blood corpuscles into four groups in respect to isoagglutination (7). Fischer says that "all known normal and pathological characteristics that are transmitted by heredity follow the Mendelian laws."

It is probable, therefore, that resistance to Rhus dermatitis may obey the laws of Mendelian inheritance, although no satisfactory proof has been shown thus far. In Mendelian inheritance three groups of characters occur, namely, recessive, dominant, and heterozygous (i. e., mixed dominant and recessive). Accordingly there are six possible different combinations of these groups, in breeding: 1, dominant and dominant; 2, recessive and recessive; 3, dominant and recessive; 4, heterozygous and dominant; 5, heterozygous and heterozygous, and 6, heterozygous and recessive.

As was stated above, among 28,756 university students 1,602, or 5.57 per cent., were treated for Rhus dermatitis. From these results one would expect that if resistance to Rhus dermatitis were inherited it would be a dominant character, as approximately only one person in eighteen is highly susceptible and, conversely, susceptibility to the disease would be recessive. With this idea in mind the dominant (relative immunity) and the recessive (high susceptibility) can be applied to Mendelian matings.

Accordingly, in a dominant and dominant mating (1) there are no cases of high susceptibility to Rhus dermatitis, nor would any succeeding generation of this order have high susceptibility. In a recessive to recessive breeding (2) all the children would be highly susceptible. When a dominant and recessive cross (3) that is, one parent but not both highly susceptible to Rhus dermatitis, the children would not be highly susceptible to Rhus dermatitis. If one parent is highly susceptible (recessive) and the other parent is heterozygous in this regard (6) then the first generation would show some cases of high susceptibility (pure recessives) and some heterozygous offsprings which would not have high susceptibility themselves, but all of whom might transmit the tendency.

It is also perfectly possible for heterozygous and dominant resistant individuals (4) to mate with one another for several generations without recessive (highly susceptible) individuals appearing; but, when heterozygous offspring of such unions mate (5) highly susceptible individuals might result. It is thus possible for a heterozygous human being to transmit high susceptibility unrevealed through an indefinite number of generations, provided he or she failed to mate with recessive or other heterozygotes, but when highly susceptibility (recessive) did appear it would be as definitely inherited as if each ancestor for several generations had been highly susceptible to Rhus dermatitis. Failure to appreciate the manner in which inherited characters may be transmitted may cause confusion.

All of the possible lines of inheritance involving Mendelian principles fit in well with what is known of the occurrence of actual cases of Rhus dermatitis. It is now apparent how there may be families all the members of which are highly susceptible to Rhus dermatitis (recessive recessive cross) how other families may be highly immune (dominant dominant cross), how when one parent is highly susceptible (recessive dominant cross), the children may not be susceptible, how when one parent is highly susceptible (recessive heterozygous cross) some of the children may be highly susceptible, how when both parents are immune (dominant heterozygous cross) the children are immune but the grandchildren may not be immune, how when both parents are immune (heterozygous heterozygous cross) some of the children may be highly susceptible.

SUMMARY

1. But little attention has been heretofore given to the possibility of hereditary natural immunity to Rhus dermatitis.

2. Animal experiments have yielded but little data so far in this regard.

3. Absolute immunity to the concentrated poison has never been proved to exist.

4. Relative immunity exists in which approximately one person in eighteen is highly susceptible.

5. This high susceptibility seems to exist in certain families and family generations.

6. Hereditary tendencies to skin diseases occur in men, e. g., benign tumors, telangiectasis, and cystic epithelioma.

7. If hereditary immunity to Rhus dermatitis exists it may be in accordance with Mendelian law for:

a. Mendel's law has been found to apply to all plant and animal inheritance so far.

b. Mendelian inheritance does appear in human inheritance, e. g., in hemophilia, in color blindness, in crossing of Europeans and Hottentots, and in the classification of red blood corpuscles.

8. In Mendelian inheritance three characters occur, recessive dominant and heterozygous. There are, therefore, six possible different matings, dominant and dominant, recessive and recessive, dominant and recessive, heterozygous and dominant, heterozygous and heterozygous, and heterozygous and recessive.

9. Resistance to Rhus dermatitis may be a dominant character as apparently only one person in eighteen is highly susceptible and conversely, high susceptibility may be a recessive character.

10. Mendelian inheritance involving these classifications conforms with and may explain the appearance of high susceptibility in some families, immunity in other families, varied susceptibility among individuals of one generation, immunity in one generation and some highly susceptible in the next.

Ivy Poisoning

CHARLES MALLORY WILLIAMS, M.D.

New York,

Attending Physician New York Skin and Cancer Hospital; Consulting Dermatologist General Memorial Hospital, New York; Professor of Dermatology, University of Vermont.

Now that summer is here and woods and fields once more tempt the town dweller to leave the noise of factories and the reek of half burned gasoline for the purer air and the quiet of a day in the open, there will come the inevitable seasonal increase of ivy poisoning. Whether in city or country practice, the physician expects this, for poison ivy grows as luxuriantly in the city park as over the old stone wall, and ignorance of botany is not confined to city dwellers. In Northeastern America there are two plants which stand out above all others in the importance of their irritant action on the skin, for although there are many which have been known, in isolated instances, to produce dermatitis, these others are harmless to the great majority of the population.

TWO POISONOUS PLANTS

Our two poisonous plants are the poison ivy, Rhus radicans or Rhus toxicodendron—for it appears in botanies under both names—and poison sumac, Rhus venenata. Rhus radicans is closely related to, if not identical with, the Rhus diversiloba of the Pacific slope; but whereas the latter often forms thickets six feet high or more, rising from the ground without support, I have never seen the former take on this manner of growth. Poison ivy may trail over the ground and carpet a considerable area, but under such conditions seldom rises more than a few inches. When, however, it finds support—such as a wall, a fence post, or a tree—it straightway climbs, and once it has reached the freedom of the air it throws out tough woody stalks and branches an inch or more in diameter. I have seen it rising three or four feet from the top of a wall and throwing out free growing lateral branches five or six feet long from the trunk of an old tree. The plant is easy to recognize, once the distinctive features have been learned, but a full description would be out of place here. It may be worth noting, however, that its leaflets are always in groups of three—the harmless woodbine has five leaflets—and the leaflets are rather thick, shiny and usually entire, though occasionally a leaflet may show the formation of an imperfect lobe.

The poison sumac, though closely related, is an entirely different plant and rather hard to recognize. Like all the other sumacs it has a compound leaf of many leaflets, but in the nonpoisonous kinds the midrib is only slightly curved and the leaflets grow out almost flat from the midrib; while in the poison sumac the midrib is decidedly curved and the leaflets do not grow out flat from each side of the rib but rise as they grow out, forming a sort of trough. The poison sumac is fond of swamps and seldom or never grows on dry soil. Its fruit is borne in loose clusters: any sumac bearing a dense conical fruit cluster—a barb, as it is commonly called—is not poisonous. It is said that the poisonous principle of the ivy and the sumac are not identical, but the symptoms they produce are practically the same. Poisoning by sumac is comparatively rare, as the plants are seldom encountered and they do not tempt the wayfarer from the beaten path except in the early fall, when the leaves surpass all others in the beauty of their pastel coloring.

The toxic principle is found only in the sap, but sap, fresh or dry, is found in or on practically all parts of the plant and there is no distinction to be made, as regards poisonous properties, between root, stem, and leaf. Its distribution, chemical and physical properties have been very carefully studied by McNair, whose monograph (1) should be read by every one interested in the subject.

MODE OF INFECTION

The most common mode of infection is by direct contact between the skin and some part of the plant. An injury to the skin does not seem to be essential but apparently there must be some injury to the plant so that sap, either fresh or dry, may be on the surface. Casual brushing against an uninjured leaf seems to be harmless, while touching a stone or tree from which the vine has been torn is very dangerous, as the surface is covered with broken aerial rootlets. There are authentic records and experimental proof of poisoning by smoke, the poison being carried on particles of soot, but not as vapor. In a large number of cases the contagion is mediate, that is, the poison is carried from plant to person by a third object. The commonest example of this is the infection of the penis by the hand of the patient, and so frequent is this that a vesicular dermatitis of the hands accompanied by a similar dermatitis of the penis is almost certainly caused by ivy poisoning, even though evidence of exposure may not be ob-

tainable. The next most common carrier is some article of clothing, a good example of which occurred in my own person. I had spent an afternoon one fall tearing ivy from some old apple trees, not touching the vines with my hands but using an axe, both for cutting and as a hook. Climbing into the trees, it was often necessary to brace myself with arm and elbow to get a good support. A week or ten days later both arms were in full eruption, swollen, red, and weeping. A month later I put on the same flannel shirt, which meantime had been laundered, and wore it for a day but did not go near any ivy or near any object where ivy had grown. By evening the skin had begun to itch, and the eruption returned as bad as ever, and in the same location. The shirt was then burned and I have had no similar attack since.

IMMUNITY

As far as we know, there is no absolute immunity to ivy poisoning though the susceptibility varies enormously from person to person, and in the individual from time to time. Even people supposed to be refractory will succumb when the concentrated poison is placed upon the skin. A patient of mine often boasted of her immunity, and once in a spirit of bravado rubbed the leaves over her face and hands as she had done with safety many times before—but this time it was different, and she stayed at home for a week, though she had to forego the best dance of the season. We do not know the cause of these variations, but I believe there is evidence that a person who has once been badly poisoned is thereafter more susceptible than before.

SYMPTOMS

The following description of the course and symptoms of an attack of ivy poisoning has reference to those produced by Rhus radicans. I believe those produced by Rhus diversiloba and by Rhus venenata are similar, if not identical, but of this I have no personal knowledge. There is always an interval between the time of contact of the poison with the skin and the first appearance of symptoms, and this may vary from a few hours to nine days. The length of this interval appears to be dependent in part on the amount of poison deposited on the skin, in part on the susceptibility of the patient, in part, perhaps, on the condition of the skin—though this last is uncertain. It is generally believed that the skin is more susceptible when in a violent perspiration than when dry, but I know of no definite evidence on this point. The first symptom is a moderate itching or burning sensation on the part affected, soon followed by an eruption of small vesicles. At first there is no redness and no perceptible swelling. From this point the course of the attack varies enormously in different cases, and no one description will answer for all. The simplest way is to describe two classes, but it must be understood that this is for convenience only and that the classes shade into each other by insensible gradations.

First, there are the abortive cases, characterized by the eruption of a few tiny vesicles or papulovesicles on some part of the body, usually a hand. There is no diffuse swelling, no general redness, the discomfort is not severe and the discharge when the vesicles rupture is insignificant. In a few days the attack is over, and the diagnosis can hardly be made except with a definite history of exposure.

Very different are the severe cases. They may begin in the same way, but the eruption spreads with the appearance of more and more vesicles, both beyond and within the affected area. The vesicles are so close set as to touch each other, leaving no areas of normal skin between, but the individual vesicles, as a rule, remain small. At the same time, the skin becomes red and swollen, the swelling being deep and boggy, though the skin does not pit on pressure as it does in the edema of nephritis. Although the swelling may be very great, the skin never acquires the leathery quality so characteristic of chronic facial eczema. The swelling is not confined to the area covered by vesicles, but may extend an inch or two beyond it. The color is usually pink and lacks both the brilliant red and the sharp margin of erysipelas. It may be several days, even a week, after the first vesicle has appeared before the disease acquires this character, while in other cases the development may take hardly more than a day. As the vesicles increase, some of them rupture and soon the skin is bathed with a constant and profuse exudation of serum, while the discomfort becomes almost intolerable. This discomfort is not the intense itching of scabies—excoriations are not a feature of the disease—but rather a combination of itching, burning, heat, weight, increased sensitiveness to touch, and interference with motion. With these local symptoms, there is also a fever, which may rise to 104° F., and the prostration which goes with it. The duration of these severe symptoms is variable, but ordinarily they recede in a week or two after reaching their climax—the swelling and the redness subsiding, the vesicles disappearing, and finally the superficial epidermis peeling off in large flakes or sheets.

There is some evidence that a severe attack confers a temporary immunity, Lyon (2) reporting that although he was very susceptible he never had a second attack the same year. This is contrary to my own experience, as recorded above, and the question needs further study. It is popularly believed that the eruption may recur from time to time, even for many years, without fresh exposure, but it is probable that such cases are to be explained either by unrecognized contact with the vine itself or by contact with some article which has been contaminated by the poison—perhaps a pair of shoes, gloves, or a walking stick.

TREATMENT

Innumerable are the methods of treatment which have been tried. Some are aimed at reducing the susceptibility by administering drugs, of which dulcamara has been one of the most popular. Others are local applications, intended to reduce the inflammation—such are the familiar calamine lotion and the equally familiar Lassar's paste—but for this purpose all alike are vain. Indeed, fatty preparations are worse than vain, for they dissolve the poison and instead of removing it they spread it over previously healthy skin. The first real progress was made by Pfaff (3), who isolated a substance which had all the toxic properties of the whole plant, soluble in fats, in ether, in alcohol and in gasoline, and which could

be removed by scrubbing with soap and hot water. This substance he called toxicodendrol, and it is probably identical with the lobinol later isolated by McNair. The method of treatment he advised is simplicity itself, and has the advantage of cheapness and almost universal availability. It is simply repeated washing with running warm water, using plenty of soap and a scrubbing brush, gauze, or absorbent cotton, depending on the toughness of the skin attacked. If running water is not available, the water in the basin must be changed repeatedly and at frequent intervals. Similarly, the scrubbing brush must be washed repeatedly with soap and warm water in the course of the treatment, and the gauze or cotton replaced frequently with fresh pieces. Unless these precautions are followed, some of the poison will inevitably remain on the skin, and in a susceptible person even a trace is enough to produce a dermatitis. If this treatment is followed within a few hours of exposure, even a susceptible person will escape, and it is capable of aborting the attack in the vast majority of cases, even when the vesicles have appeared—but of course the earlier it is used, the better. It has little effect in established severe cases.

In 1906, Acree and Syme (4), writing on the composition of texicodendrol, found that early and repeated use of one per cent. or two per cent. solution of potassium permanganate, especially if hot and containing a little sulphuric acid, was very effective in checking and aborting an attack. The drug acts by destroying the poison by oxidation. I have not tried this preparation myself, and would expect to find it useful only in the class of cases that are successfully treated with soap and water.

The next step in advance was the use of a tincture prepared from the plant, as advocated by Schamberg (5). This method of immunization was further elaborated by Strickler (6), who added the intramuscular injection of a Rhus antigen. The method he advised is as follows: For immunization he gives four intramuscular injections of 0.3 to 0.5 c. c. each of Rhus antigen at intervals of three or four days. After the last dose, the patient takes from five to ten drops of tincture of Rhus, well diluted, three times a day, after eating, for a period of one month. In treating an attack, he injects from .3 c. c. to .5 c. c. on two successive days, and follows this, if necessary, with two or three more injections of .3 c. c. to .7 c. c., at intervals of two to three days. The results to be obtained by this method are nothing less than brilliant, and are well illustrated by the following cases:

Case I.—A young woman, R. G., who had had an attack of ivy poisoning in 1920, came to the New York Skin and Cancer Hospital on July 2, 1923. She had been exposed to ivy on June 24th, and on the following day noticed blisters on the wrists, which gradually spread till a large part of the surface was involved. Her temperature on admission was 101°. She was given five minims of tincture of rhus three times a day, and received by injection 0.3 c. c. of the antigen, diluted in one c. c. of salt solution, July 3rd; 0.45 c. c. on July 4th; 0.2 c. c. on July 7th, and 0.4 c. c. on July 11th, when she was discharged cured. The eruption began to improve after the first dose.

Case II.—Another young woman, S. K., came to the hospital the same day. Her eruption had been present about two weeks, having developed five days after exposure in Van Cortlandt Park. Her temperature was 101.6°. The left hip and thigh was one mass of close set vesicles, many of which had ruptured, producing a copious excretion of serum, which actually dripped on to the floor as she stood up for examination in the dispensary. There were other vesicles scattered over the left foot and arm and over the back. She received five drops of the tincture of rhus three times a day, and injections of the antigen on July 2d, 3rd, and 5th. No new vesicles appeared after the third dose, and recovery was rapid and uneventful.

Case III.—Mr. J. L., forty-one years old, came to my office on July 16, 1923. He had been in the country over July 4th, and about July 9th noticed an itching of the buttocks. This gradually increased, and by July 13th there was a good deal of swelling. When I first saw him, the projection of the buttocks was hard, tense, brawny, dull red in color, and studded with tiny vesicles. The condition suggested an acute inflammatory swelling, but although there was much burning and itching there was neither pain nor great tenderness. On the abdomen there were irregular groups of vesicles on an erythematous base, the erythema being more extensive than the vesiculation. There was a group of vesicles on the ulnar border of the left wrist, and two vesicles on the glans penis. Washing with soap and warm water and dressing with a saturated solution of acetate of lead in seventy per cent. alcohol gave little or no relief, and on July 18th he received 0.5 c. c. rhus toxicodendron antigen in the left buttock. There was moderate pain from the injection, lasting till evening. The swelling began to subside notably about nine hours after the injection, and next day the oozing of serum had ceased and the whole eruption was resolving. He received a second injection of 0.5 c. c. of rhus antigen, and did not report again.

The treatment may therefore be summarized as follows: First, and most important, let every one learn what these two plants look like and avoid them. Second, wash thoroughly, as directed above, after every exposure, and also on the first appearance of the eruption, taking, in the latter case, three drops of tincture of rhus three times a day. This will be enough for the majority of cases, but in the severe types, whenever seen, and in the milder types which are growing worse in spite of washing and the tincture, use both the antigen and the tincture.

Phenolphthalein Eruption

E. W. NETHERTON, M.D.,
Cleveland,
Department of Dermatology, Cleveland Clinic

Since Abramowitz demonstrated that some of the cases heretofore diagnosed as erythema perstans, toxic erythema or recurrent erythema multiforme, were in fact produced by the ingestion of phenolphthalein, dermatologists have seen and recorded several additional cases. However, the reported cases are still few in number and since, with few exceptions, these reports have appeared in dermatological journals which are not often read by the general practitioner, this report of a case together with a brief review of the literature is offered.

REPORT OF A CASE

Case.—The patient, a young woman, eighteen years of age, was first seen on September 14, 1923. She complained that for the past few months she had had recurrent attacks of an eruption which was first limited to the neck but in subsequent attacks had extended to the body. The eruption was accompanied by itching and burning but there were no constitutional symptoms either before or during the attacks. The eruption would usually disappear in a week or ten days leaving pigmented areas in which the eruption always recurred. The patient was accustomed to taking liquorice powders as a laxative but occasionally she took the ex-lax instead. She had not noticed any relation between occurrence of the eruption and the taking of the ex-lax tablets. The general health of the patient was excellent except for constipation and painful menstrual periods. Her past history was negative except that at the age of eight she had had pneumonia followed by empyema.

The physical examination disclosed numerous slightly grouped, macular plaques, scattered over the trunk, being most numerous on the lateral surfaces. The neck, face and extremities and the mucous membranes were not involved. The lesions varied in size from one half inch to several inches in diameter. The color ranged from purple to bright red. The larger lesions were purple at the centre, changing to various shades of red at the periphery where in some there was a distinct areola. The larger plaques were slightly raised above the level of the skin. Some of the lesions had become confluent. There was some desquamation in the resolving lesions but the more acute lesions were smooth. On the right side there was a large depressed scar, the result of an operation for empyema, the anterior portion of which was included in one of the plaques. The scar tissue showed the same amount of inflammatory reaction as the adjacent skin.

The laboratory findings were as follows: Urine: neutral, specific gravity 1020, slight trace of albumin, otherwise negative. Blood: red blood cells, 4,410,000; white blood cells, 5,000; hemoglobin 80 per cent. (Dare); Wassermann negative. Blood chemistry: three hours after meal—sugar 104, urea 33.

The patient was instructed to take calomel, two grains, in fractional doses, with magnesium sulphate on the following morning and a bland application was given for local use. When seen three days later the subjective symptoms had disappeared and the resolution of the eruption was well under way.

On September 24th, ten days after her first visit, the character of the plaques had changed a great deal, most of the inflammatory appearance having disappeared, leaving pigmented areas. At this time one grain of phenolphthalein was given and the patient was advised to return if any change was noticed. The next morning she returned, complaining of severe itching and burning of the skin. The pigmented areas presented the same polychromatic inflammatory plaques that were present at the time of the first observation. New lesions had appeared but they were smaller and of a brighter red than the larger and older lesions. The patient was instructed to avoid proprietary remedies as many contain phenolphthalein, and general measures for constipation were prescribed. On December 13th the pigmented plaques were still present but they were gradually disappearing. At this time cutaneous tests for phenolphthalein were negative. The skin was scratched and powdered phenolphthalein with a drop of water was rubbed on the abrasions, and the patient was directed to take two grains of antipyrin three times a day for seven days. At the end of this period there was no change in the character of the lesions.

Since the patient stopped taking ex-lax tablets or phenolphthalein in any other form, there has been no recurrence of the eruption.

REVIEW OF THE LITERATURE

Cases of phenolphthalein eruptions probably occur more frequently than is generally supposed as many are probably unrecognized. Judging from the number of cases presented before the various dermatological societies, however, the condition may be considered as being comparatively rare.

In 1918, Abramowitz (1) first showed that phenolphthalein may produce an eruption. He described five cases of persistent erythema multiforme associated with pigmentation but in only one of these was he able to prove that phenolphthalein was the etiological factor. Several weeks later this case was shown by Dr. Howard Fox (4) before the Manhattan Dermatological Society, at which time the patient presented several pigmented rounded macules, varying in size from that of a bean to that of a silver dollar. The source of the phenolphthalein in this case was ex-lax which the patient was in the habit of taking as a laxative.

Ayers (2) reported a case in which the lesions were limited to the face, in contrast to the majority of the reported cases in which the trunk was the principal site. Ayer's article includes an excellent discussion of the pharmacology of phenolphthalein.

In 1922, Wise and Abramowitz (6) published a

complete review of previously reported cases with four additional cases of their own. They also cited three cases which were presented by MacKee and Wise before the Manhattan Dermatological Society and the New York Academy of Medicine in 1916 and 1917 under such titles as Erythema Multiforme

Fig. 1.—Scattered, somewhat grouped, polychromatic macules and plaques, produced by the ingestion of phenolphthalein. Note the empyema scar part of which is included in a plaque.

Perstans, Melanoderma from Recurrent Erythema Multiforme, and Toxic Erythema, and express the opinion that these cases were in reality cases of phenolphthalein eruption, for although at the time of the presentation the etiological factor was unknown and in only one was there any definite history of the ingestion of phenolphthalein with accompanying exacerbation of the eruption, the clinical picture indicated that they belonged in this group. These authors are of the opinion that antipyrin may produce an eruption identical with that caused by phenolphthalein and they also mention the close similarity between these and the fixed arsphenamine eruptions.

Corson and Sidlick (3) reported a case of urticaria which was caused by phenolphthalein. Their patient had taken a proprietary tablet (composition unknown) for constipation for over two years without any apparent ill effects. However, she developed urticaria following the third inoculation for typhoid prophylaxis. The eruption disappeared when the laxative tablets were discontinued, returning two months later when the laxative tablets were again taken. The authors were able to reproduce the urticaria by the administration of one grain of phenolphthalein.

Rosenbloom (5) observed a case in which herpes of the nose could be produced by the ingestion of as small a dose as one half grain of phenolphthalein.

Wise and Abramowitz (6) think that the eruption is produced by a split product of phenolphthalein rather than by the drug itself. Pollitzer, in discussing this article, is of the same opinion and suggests that the split product is probably produced in the digestive tract or in the blood.

TYPE OF ERUPTION

The clinical picture presented by the cases of phenolphthalein eruption so far reported is so uniform that it is probably safe to consider this condition a distinct type of dermatitis.

The eruption, as in the author's case, consists of numerous scattered, somewhat grouped, irregular polychromatic macular plaques, varying in size from a pinhead to a coin, or the palm of the hand. The color varies from pink to bright red, dusky violaceous and deep purple. The central portion of the plaque is usually violaceous with change in color towards the periphery where a pink or bright red areola may be present. With exacerbation the plaques may enlarge peripherally and become confluent or new macules may develop near the peripheries or upon the unaffected area. As the attack subsides the affected areas become pigmented and remain so for many weeks. During resolution slight scaling may occur. Vesiculation, erosion and superficial ulceration may occur, especially on the mucous membranes of the mouth and on the skin of the genitals.

The subjective symptoms of itching and burning may be either moderate or severe and mild constitutional symptoms may accompany the eruption. Relapses may follow the ingestion of phenolphthalein with the reappearance of the eruption on the sites of the primary lesions, sometimes with new lesions elsewhere. This type of lesion seems to be character-

Fig. 2.—The same eruption as that in Fig. 1, showing the desquamation which often accompanies the evolution of the plaques.

istic of dermatitis medicamentosa produced by phenolphthalein. Clinically it is a persistent erythema multiforme.

CONCLUSIONS

An additional case of dermatitis medicamentosa produced by phenolphthalein is reported.

The cases so far observed have presented such a

uniform eruption that it may be safe to consider phenolphthalein dermatitis as a distinct clinical picture.

Antipyrin may produce an eruption identical with that seen in these cases but the eruption produced by this drug is usually morbilliform, erythematopapular, scarlatiniform or urticarial in character.

The socalled fixed arsphenamine eruptions are usually pink instead of polychromatic and have more sharply defined borders. As Wise and Abramowitz have aptly stated, these fixed eruptions may often be due primarily to phenolphthalein, the patient having taken this type of laxative following arsphenamine without informing his physician.

In all cases which present an eruption consisting of polychromatic macular plaques which terminate in pigmented areas and with a history of recurrence at these sites, a tentative diagnosis of phenolphthalein dermatitis should be made. The possibility that phenolphthalein may be the etiological factor should be ruled out before any other diagnosis is suggested.

In cases of chronic urticaria and recurrent herpes phenolphthalein should be considered as an etiological possibility.

Patients who are susceptible to phenolphthalein should be advised not to take proprietary laxatives as most of them contain this drug.

Treatment of Acne Vulgaris*

OSCAR L. LEVIN, M.D.,
New York,
Instructor and Chief of Clinic, Department of Dermatology and Syphilology, Cornell University Medical School and Clinic

Acne vulgaris is a complex of cutaneous lesions depending upon an abnormal heaping up of excessive numbers of stratum corneum cells and an abnormal, increased function of the sebaceous glands. Associated with these external manifestations, there are certain fairly constant constitutional symptoms. The whole picture is contingent on the disturbance in metabolism which develops consequent to delayed or perverted endocrine function during the period of adolescence.

In a study of the biochemical status of patients with acne vulgaris, it has been found that more than one half showed hyperglycemia or a high normal blood sugar. In about one third a low alkali reserve existed, and the feces from more than eighty per cent. of the patients showed carbohydrate fermentation. Most of the cases in which the metabolic rate was determined, showed a slight increase.

In a paper (1) read before this society just four years ago, I described the various constitutional and local procedures employed in the treatment of acne vulgaris. Since then further clinical studies and the previously mentioned laboratory experiments have corroborated the views expressed at that time. However, due to the advances made in the treatment of these patients by means of the x rays, it is advisable to review this subject. In order to save time and space, only the most important points in the general treatment of the patients will be emphasized and the x ray therapy described.

CONSTITUTIONAL TREATMENT

The constitutional treatment of acne vulgaris consists, mainly, in the correction of the diet, gastrointestinal supervision, prescription of general tonic measures and the administration of alkali and organotherapy.

DIET

The diet is made almost carbohydrate free. Sugar, candy, cake, pies, icecream, pastries, puddings, jam, jelly, cocoa, potatoes, cereals and sweet fruits are forbidden. Hard, irritating and fried foods are interdicted, as they interfere with proper digestion. Spices and condiments, alcoholic and stimulating beverages, like coffee and strong tea, are also prohibited as they tend to cause reflex dilatation of the cutaneous vessels and thus increase the congestion of the skin. Milk, cream, fermented milks, eggs, and vegetables should constitute the main foods. Meat or fish once a day, cheese, cool soups without flour, and no more than six slices of bread, each half an inch thick, complete the diet and suffice to provide ample nourishment as well as satisfy the patient's appetite and whims. Large quantities of water should be taken at regular intervals during the day to aid elimination through the kidneys and the skin. Most acne patients should be overfed and those who are underweight should be advised to drink three eggnogs daily between meals.

MEDICINAL TREATMENT

The care of the gastrointestinal canal consists, in most cases, of the application of the usual measures to overcome the constipation, to relieve the gastric hyperacidity and to remove the intestinal fermentation.

ORGANOTHERAPY

In the treatment of acne with organotherapy, it has been found that no one single gland will give a

*Read at a regular meeting of the Eastern Medical Society, New York Academy of Medicine, October, 1923.

constant result. Lutein, however, often seems to benefit those individuals with menstrual acne. Thyronucleoprotein is sometimes of temporary benefit to those individuals who seem sluggish; but if it is continued for too long a time, pustules appear in greater numbers. These tablets frequently give results where there are deep indurated infiltrated masses, and favor absorption of that obstinate type of nodular acne which, if neglected, tends to become necrotic. Adrenonucleoprotein is used in cases accompanying exophthalmic goitre.

TREATMENT OF ACIDOSIS

For the treatment of acidosis, the usual procedure is employed. Gratifying results often follow the administration of a powder consisting of potassium citrate, calcium lactate, magnesium oxide, and bicarbonate of soda.

VACCINES

Further experience with vaccines substantiate the conclusions which I have expressed in former papers. They are of no value in the treatment of acne vulgaris, excepting in rare instances when an autogenous or stock mixed staphylococcic vaccine will favor the disappearance of furuncular lesions.

X RAY THERAPY

During the past three years, I have used intramuscular injections of turpentine in conjunction with x ray therapy to hasten the absorption of deep, boggy lesions. Here it may be stated that the use of the x rays marks a memorable advance in the treatment of acne vulgaris. In former times, it was impossible to prognosticate positively the time and expense which would be necessary in the cure of a case of this kind. At present, however, it is possible to tell our patients that with proper supervision of the general condition and the local use of the x rays, a cure may be accomplished in ninety-eight per cent. of the cases within three to four months.

The apparatus employed for x ray therapy includes any standard interrupterless transformer with perfect metres and a Coolidge tube. The technic followed consists in the administration of fractional doses of x ray by the method of indirect measurement.

The patient is placed in the recumbent position and the face turned to one side. The scalp, the ears, the eyes and the eyebrows are covered with leadfoil and the chest and neck with lead rubber. The tube is then brought toward the face and inclined so that the anode is at right angles to an imaginary line drawn through the outer part of the zygoma. The skin distance, that is, the distance between the anode and the skin, is usually accepted at eight inches. A dose of one quarter of a skin unit of unfiltered rays is administered. The same dose is then applied to the opposite side. Finally one eighth of a skin unit is given to the middle of the face. It is advisable to give this last exposure even in the absence of lesions on the forehead, nose, and chin to insure against the future development of an eruption in these areas. When the back is affected each half is given one quarter of a skin unit. The shoulders and arms are exposed at the same time but precautions are taken to shield untreated regions. The same procedure is followed for the treatment of the chest.

The exposures are given once weekly for a period of twelve to sixteen weeks. At times no effect of treatment may be noted until after the eighth seance. Occasionally the lesions seem to become more active after the first two or three exposures, but this increased inflammatory reaction rapidly subsides. As a rule no more than sixteen treatments are necessary, but in the presence of very stubborn lesions without any erythema or atrophy, and especially if the skin continues to feel greasy, the course may be prolonged to the twentieth week. Always note the presence or absence of grease. If the skin becomes very dry the number of exposures should be reduced. Excessive dryness is not permanent.

Freckles and patches of increased pigmentation developing during the course of treatment do not contraindicate the continuance of treatment. These develop most often in brunettes and disappear after the cessation of treatment.

Relapsing lesions, when they do occur, usually appear about six months after the termination of treatment and rarely do they require more than six exposures to remove evidences of the disease permanently.

SCARRING

Regarding the question of scarring, it may be stated that the x rays neither cause nor increase the scars. These are the results of old comedones or deeper lesions and can be avoided by early institution of treatment. Neither is hypertrichosis caused by the rays. When present it is an accompanying condition and associated with the endocrine disorder. Telangiectasia are never observed and atrophy is very rare when proper technic is employed. Atrophy is first evidenced by a fine wrinkling on the cheeks and chin near the corners of the mouth and calls for postponement or discontinuance of x ray therapy.

The best results are obtained in the indurated cases and the rare failure in the punctate type. In the latter instances a strong sulphur lotion or a bethanaphthol ointment combined with mechanical expression of the blackheads should be tried. Another type of eruption which may give an untoward result is that in which there is an acneiform dermatitis. In the management of these cases the gastrointestinal condition should be corrected, the intestinal fermentation removed and the gastric acidity reduced.

The rays should not be employed promiscuously. One who uses them for therapeutic purposes should be able to interpret the clinical symptoms in terms of their microscopic pathology. The operator should possess an exact technic and knowledge of the microscopic changes produced by the rays on the structure of normal and abnormal skin.

RADIUM

Radium has been applied with success in the treatment of acne but holds no advantage over the x rays. Besides, it is not practical and convenient.

LOCAL TREATMENT

All patients receiving radiotherapy should be warned against the local use of, or exposure to, any form of irritant. The rays are never administered subsequent to the application of an irritant for at least a fortnight. Alcohol, witchhazel, tar, sulphur, salicylic acid, resorcin and all keratolytics are interdicted for local use. Mild soaps, zinc oxide ointment

and calamine and zinc oxide lotion may be employed. A weak solution of phenol may be added for antiseptic and antipruritic effect. The affected parts should be washed frequently with cold water and a neutral soap and the blackheads expressed gently without injury to the surrounding skin. Seborrheic eczema complicates almost every case and this should be treated. However, in the application of the antiseborrheic and stimulating applications to the scalp precautions should be taken to avoid irritating the face. Subsequent to the cessation of radiotherapy a calamine and zinc oxide lotion may be dabbed daily on the face, and if an oily condition persists a mild sulphur lotion may be begun after one month. The other methods of local treatment have been described in the paper already mentioned and to which the reader is referred.

CONCLUSIONS

In conclusion it may be stated that the introduction of the x rays in the treatment of acne vulgaris has changed the outlook on the ultimate outcome. The patient may be assured of a prompt and positive cure. The administration of fractional doses of x rays removes the hyperkeratosis and reduces the abnormal sebaceous gland function. The lesions disappear and the skin is made less susceptible to the obnoxious factors acting on it from within. While the visible evidences of disease are being removed, the internal derangements are corrected by constitutional treatment. When x rays are properly employed there is no fear of any danger. It is emphasized that the patient as well as the acne should be treated. Search should be made for any constitutional disorder and corrected in order to obtain a prompt cure and to prevent relapses.

The Buccal and Lingual Mucosa in Neurosyphilis

B. LANDIS ELLIOTT, M.D.,
and PAUL F. STOOKEY, M.D.,
Kansas City, Mo.

ETIOLOGY

The etiology of leucoplakia has long been a matter of controversy. Most observers consider syphilis, associated with some irritant, the most probable etiological factor, although all are frank to admit that they frequently encounter an extensive leucoplakia in an individual in whom the clinical diagnosis of syphilis cannot be substantiated. The French accept leucoplakia as prima facie evidence of syphilis even in the absence of supporting clinical or laboratory evidence. The Viennese school insist that leucoplakia is associated with syphilis in over ninety per cent of the cases. Ehrmann (1) teaches that the tissues of the syphilitic respond to any irritant to an abnormal degree and this fact explains the frequent association of syphilis and leucoplakia. Kyrle (1) is in accord with this view and states that in ninety per cent. of his cases he is able to find other clinical or serological evidence of syphilis. Among our own observers Ormsby and Sutton (2), McBride and Dennie (3) are convinced of the frequent association of syphilis and leucoplakia. Osler's (4) statement with regard to leucoplakia, that "most of the patients have had syphilis," is significant. Pusey (5) believes that long continued irritation will produce leucoplakia and does not consider the association with syphilis of great significance. Bloodgood (6) reports but twenty-one per cent. of his leucoplakia cases with a positive blood serum and infers that the association is accidental.

We have been impressed with the high percentage of men who show an early leucoplakia along with a positive Wassermann. This we believe to be explained by the fact that most of the cases under our observation have been young men. The leucoplakia is comparatively recent and the Wassermann is frequently positive. After the expiration of considerable time the leucoplakia persists and the Wassermann, either with or without treatment, may become negative.

There is an impression present in the French (7) literature that tabes and other manifestations of neurosyphilis are frequently associated with leucoplakia of the tongue and buccal mucosa, and the hypothesis is advanced that the presence of leucoplakia is evidence of an impending neural disaster. We have been much impressed with this observation and one of us has been for several years inspecting the mouth of every syphilitic who showed clinical evidence of neurosyphilis. The association between neurosyphilis and buccal leucoplakia was so frequent as to be startling. Unfortunately no exact data were kept until September, 1923, at which time it was decided to keep complete notes on the serological and neurological examination of every case of unquestioned neurosyphilis that came under our observation, and to study the buccal and lingual mucosa in association with the complete neurological and serological findings. No case was admitted to this series unless the evidence, both clinical and serological, was beyond question; in short, a frank case of neurosyphilis. The patients studied in this series were all young males, averaging about thirty years of age.

The existing degree of leucoplakia in our cases varied widely and as pointed out by Ormsby (8), soft infiltration representing a late secondary or early tertiary manifestation of syphilis frequently cannot be differentiated from leucoplakia. We are convinced that this clinical fact explains the occasional

favorable response to treatment noted after the administration of specific medication in leucoplakia.

CHARACTER AND EXTENT OF LESION

The entire buccal mucosa on both sides of the mouth may be of a light grayish tinge, a generalized manifestation, or the lesion may be more circumscribed along the line of occlusion running from the angle of the mouth to the third molar. This is a common and characteristic finding. The lines appear somewhat depressed as though pencilled with a stick of silver nitrate and frequently checked into small squares; difficult to describe and best compared to the checks in old pottery. The tongue is generally large and shows indentation from the teeth. Along the margin, where contact with the teeth is made, small slightly depressed areas, covered with epithelium which has a smooth glazed appearance, are frequently found at the lingual margin representing the site of some previous ulcerative process.

On the tongue the normal fissures are exaggerated and leucoplakia of any degree may occur. Exceptionally atrophic glossitis with the characteristic atrophic lingual mucosa with its peculiar glazed appearance may occur. In one of our cases the buccal mucosa showed an extensive leucoplakia, while the anterior portion of the tongue was markedly atrophic and covered by a smooth thin atrophic mucosa, causing the point of the tongue to present an appearance suggesting the point of an arrow head. W. L. McBride informs us that Hyde recognized this tongue as a rare clinical manifestation of syphilis and named the condition "arrow tongue." An accurate and comprehensive description of the buccal and lingual mucosa is difficult, but the lines that give the appearance of silver nitrate pencilling at the point of occlusion and the checkering are the outstanding features.

The lesion may involve the tongue to a greater degree than the buccal mucosa. Frequently a marked glossitis is found in association with a leucoplakia of the buccal mucosa. Careful inspection of the mouth in a good light is essential. Exceptionally a definite ulceration behind the third molar is found in association with a glossitis and characteristic changes in the buccal mucosa. Few patients are aware of the existence of leucoplakia in the mouth and the lesions must be of unusual severity to produce symptoms. Of the fifty cases of neurosyphilis studied in this series all presented characteristic objective findings along with a positive serology. Cases open to a reasonable element of doubt as to the diagnosis of syphilis were excluded.

Paresis was present three times, moderately advanced tabes six times, and the neural manifestations of vascular syphilis, clinically diagnosed as cerebrospinal syphilis, were present forty-one times. It is probable the latter group contained several cases of early tabes. Twenty cases showed an extensive leucoplakia involving the oral mucosa. Twenty-one cases showed a moderate degree of involvement of the oral mucosa with the characteristic pencilled lines along the line of occlusion. Eight cases showed slight but characteristic changes. The buccal mucosa showed leucoplakia in forty-eight cases. The tongue showed leucoplakia or glossitis but once with a normal buccal mucosa. As a rule, both the buccal mucosa and the tongue were involved, the leucoplakia frequently being present on the buccal mucosa while the tongue showed glossitis with numerous deep fissures and presented a peculiar glazed appearance. Only one case of the fifty studied presented a normal mucosa of the entire buccal cavity.

The history, objective findings, and serology, along with the description of the oral cavity in the three cases, are given representing the different degrees of oral pathology observed.

CASE HISTORIES

Case I.—Laborer, thirty-two years of age, who had a soft chancre fifteen years ago; had never received antisyphilitic treatment. He complained of headache, and pain in the abdomen at night. The location of the pain was rather indefinite but at times it was of sudden onset. He also stated that he was extremely nervous and irritable and did not sleep well. Neurological examination showed that the pupils were equal, slightly irregular, and reacted very sluggishly to light. The knee jerks were markedly exaggerated. Sensation was normal over the lower extremities. There was marked swaying in the Romberg position. Blood serum, four plus; lumbar puncture refused. Examination of the oral mucosa showed the presence of a typical and extensive leucoplakia involving the entire buccal mucosa on both sides. At the line of occlusion the leucoplakia was markedly intensified and a depressed line checked into small squares extended from the corner of the mouth to the third molar. The tongue was deeply fissured and markedly enlarged showing indentations from the teeth. The pathology in the oral mucosa was extensive.

Case II.—Hospital orderly, twenty-nine years of age, who denied all venereal disease. He complained of numerous and varied subjective symptoms along with "inability to control his eyes." The history was extensive and unusual and not of much value. A neurological examination was made showing that the pupils were round, regular, and very sluggish to light. There was a horizontal nystagmus present on looking forward which was exaggerated on looking in a lateral direction. Tongue protruded in midline. The deep reflexes were exaggerated but equally on the two sides. Abdominal reflexes were present and active. No ankle clonus, Babinski, Oppenheim, Chaddock or Gordon; no intention tremor; no incoordination or ataxia; no Romberg. The absence of speech defect and intention tremor and the presence of the abdominal reflexes excluded multiple sclerosis. The Wassermann on the blood was four plus and the spinal fluid showed globulin cell count of eighteen with a positive Wassermann. Examination of the oral mucosa showed a generalized superficial leucoplakia over the entire buccal mucosa, which is intensified at the line of occlusion. The continuity of this line is broken into numerous small squares which produces a checked appearance. The mucous membrane of the tongue was normal but the tongue was markedly enlarged and showed indentations from the teeth. The findings in this mouth were moderate but characteristic.

Case III.—A physician, forty-nine years of age, was accidentally infected with syphilis in 1905. The initial lesion was an atypical sore on the index finger of his right hand which was followed by a charac-

teristic sore throat. From this sore throat syphilis was diagnosed. Treatment extended over five years by mouth and inunction. Clinical signs of syphilis were not observed until the summer of 1918, when he had severe shooting pains followed by a typical and rapidly developing tabes. Blood serum negative, spinal fluid two plus. A neurological examination showed typical Argyll Robertson pupils, knee jerks absent, marked impairment of sensation over lower extremities, sphincters relaxed, and partial incontinence of urine present; Romberg positive. The patient did not smoke. Examination of the oral mucosa showed the presence of a slight greyish tinge over the entire buccal mucosa with loss of the normal lustre. There was a diffuse leucoplakia of slight degree, which was intensified at the line of occlusion, resembling a line drawn from the corner of the mouth to the third molar with a silver nitrate pencil. The tongue was normal. The findings in this mouth were slight but characteristic.

CONCLUSIONS

Although we have occasionally encountered an individual with leucoplakia in whom no other clinical or serological evidence of syphilis was present, we are convinced that the frequent association of leucoplakia buccalis and lingualis along with an associated glossitis is too constant to be an accidental finding and we believe that the presence or absence of these manifestations involving the entire mucosa of the oral cavity along with the associated objective findings is a valuable piece of evidence in formulating an opinion as to the presence or absence of clinical syphilis.

In our observations in fifty cases of unquestioned neurosyphilis changes in the buccal and lingual mucosa have been as constant a finding as any abnormality of the pupils.

The Pathology of Pruritus Ani, Vulvæ and Scroti*

J. F. MONTAGUE, M.D.
New York

The pathological findings in pruritus ani, vulvæ and scroti are identical in nature regardless of the region examined. Throughout the pruritic zone, that is, the area to which the sensation of pruritus is referred, we find a pathological condition of one of three types.

It will be borne in mind, however, that at some time in a certain percentage of cases even in the presence of marked subjective manifestations of which the pruritus is the chief one, absolutely no gross pathology is seen. I have observed innumerable cases in which the pruritus existed for a long time prior to any apparent tissue pathology, but have further observed that the itching is never quite as severe as when some break in epidermal continuity occurs.

The explanation of the occurrence of pruritus in an area entirely devoid of local pathological changes is explainable, to my mind, on the basis of a misreferred sensation entirely analogous to the misreference of pain. This theory is elaborated upon in my article (1).

Needless to say, these cases, with pruritus present but no objective manifestation, are of comparatively recent occurrence, for sooner or later a pathological condition does develop which finds classification as one of the types described later.

The particular findings in any one of the types described below are modified in degree and extent according to the time the condition has existed, because the changes are progressive and in direct proportion to the duration of the disease or its complication by other features.

The first type represents a subacute or chronic dermatitis of traumatic origin and is often the predecessor of the second type to be described. An examination of the skin in the pruritic zone in this type shows, in an early stage, an abnormal smooth fullness of the skin with a diffuse, dry, shiny redness. The skin also seems somewhat thicker and tougher than normal. Later the integument assumes the appearance of wet leather or pig skin, and is thick, tough and indurated in consistency. All natural ruddiness has departed from the skin, as well as the normal pigment, and it looks moist, soggy and of a grayish white color. The skin may become lichenified or hyperkeratotic, and, furthermore, because of hypertrophy it quite often becomes folded into broad radial creases, folds or ridges with consequent accompanying sulci between them. In these sulci a thin, watery fluid collects and this moisture being an abnormal condition naturally irritates and causes a progression of pathology. In early cases no lesions are evident, the skin being quite evidently unbroken. These changes are particularly evident in the anterior and posterior raphe. The pruritic zone in very chronic cases has fairly welldefined borders and appears circumscribed. In cases of pruritus ani the mucocutaneous margin is not fissured, but both this region and the lower three quarters of an inch of the anal canal appears congested. The sphincter is in the majority of cases slightly hypertonic. The pathological diagnosis in such a case is that the condition is a chronic dermatitis probably of traumatic origin.

My interpretation of this stage is that it represents a normal reaction on the part of the skin and mucous membrane of this region to the rubbing, scratching and other irritation to which it is subjected by the patient in his attempts to relieve, annul or inhibit the sensation.

The second type is that in which bacterial invasion is quite evident. The continuity of the skin is de-

*Read before the New York Pathological Society, December 13, 1923.

FIG. 1

FIG. 2

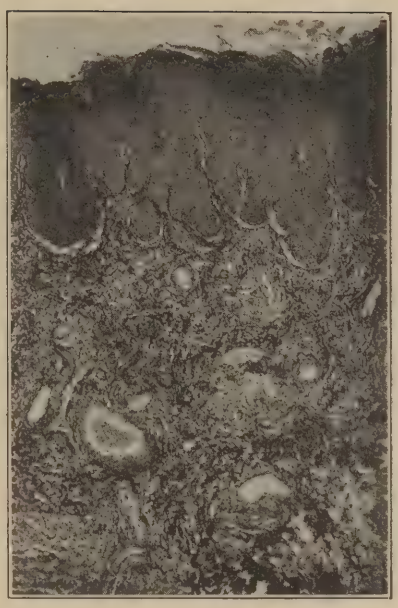

FIG. 3

FIG. 1.—Clinical diagnosis: Anal pruritus without evident lesions of the skin. Histological diagnosis: Chronic productive dermatitis. Features: Some hyperkeratosis, marked hyperplasia of the stratum mucosum with increased pigmentation; extensive increase in the interpapillary downgrowths; marked diffuse round cell infiltration of the corium; marked increase in the fibrous connective tissue element of corium. A large tactile corpuscle is to be seen. The tactile corpuscle of Meissner is seen surrounded by cellular infiltration. The walls of the bloodvessels seem sclerosed but there is no endarteritis.

FIG. 2.—Clinical diagnosis: Anal pruritus of great chronicity but no lesions of the skin evident. Histological diagnosis: Chronic productive dermatitis. Features: Hyperkeratosis, hyperplasia of stratum mucosum, great downgrowth of interpapillary processes; marked sclerosis of the fibrous connective tissue element of the corium. A tendency toward hyalinization of the epidermal cells is noted. Stain: Hematoxylin and eosin.

FIG. 3.—Clinical diagnosis: Anal pruritus without skin lesions. Histological diagnosis: Chronic productive dermatitis. Features: Marked sclerosis of the fibrous connective tissue of the corium extending up into the papillae. Stain: Picrofuchsin.

cidedly broken by abrasions and excoriations resulting from attempts to relieve. It, therefore, looks a dull red and has a cracked surface from the fissures of which oozes a sticky exudate. Sometimes a diffuse rose colored skin surface, over which is scattered moist, red, concave erosions, is seen. These erosions ooze serum profusely. In the interval between the fissures previously mentioned, the skin occasionally shows a minute vesiculation or more often considerable scaling of the epidermis. When the condition has reached the stage where it may be termed subacute or chronic, the changes in the skin are more pronounced and the area involved appears a dull red and feels harsh and rough to the touch. It is thick, tough and indurated in consistency. The infiltration and induration are similar to that usually caused by the deposition of an inflammatory exudate in a tissue of a low degree of vitality. In cases of pruritus ani the mucocutaneous margin is quite often fissured, sometimes in a multiple manner; the sphincter is decidedly hypertonic, and the mucous membrane of the lower three quarters of an inch of the anal canal deeply congested, dry and tough. Pathologically this condition is a subacute or chronic dermatitis probably of infective origin.

The relation of these two types to each other is variable. In the majority of cases the first precedes the second, but in many cases the disease starts without the occurrence of traumatic dermatitis.

In the third type we notice that the skin is evidently the seat of atrophic changes. It has become depigmented or has less of a soggy appearance and is of a grayish white color. The hypertrophic folds of the other types are present but less marked; they have, however, lost their natural ruddiness and the whole skin seems thinner. The sphincter may or may not be hypertonic. The lower three quarters of an inch of the anal canal is harsh, white and leathery. Pathologically, the condition is one of kraurosis.

MICROSCOPICAL PATHOLOGY

When tissue from the pruritic zone in a series of cases of this disease is subjected to microscopical examination the pathological findings are found to be one of three types:

1. In a certain minority percentage which are seen clinically early, even though the pruritus is intense, there is no pathology of any sort whatever; the tissue is normal. This type corresponds with the type in which no gross pathology is found. Needless to say, this type merges into that of the succeeding one.

2. In those cases which, in the gross, present evident pathology but no evidence of impairment of epidermal integrity the following processes are to be found: Hyperkeratosis; a thickening and proliferation of the stratum mucosum due to hyperplasia. Consequent upon this there is a great growth downward of the interpapillary processes (Figs. 1 and 2). Connective tissue hyperplasia (Fig. 3) is also present and a marked sclerosis of the connective tissue of the corium occurs which extends well up to the base of the papillæ and even up into the papillæ themselves. Figs. 3 and 4 are specimens of such cases stained by Van Gieson stain which, of course, shows up particularly well the connective tissue in a section. The bloodvessels are not dilated but are surrounded as is every other structure in the corium, by a collar of sclerosed connective tissue. Scattered infiltration of the corium by a cellular element which is composed chiefly of round cells, also occurs. This

Fig. 4

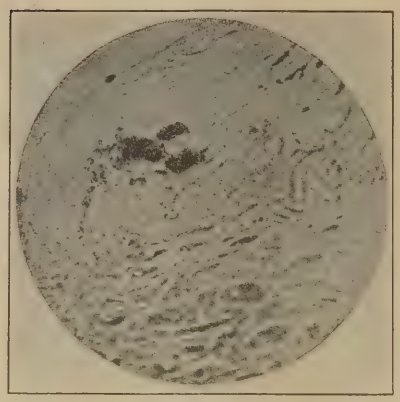

Fig. 6.

Fig. 4.—Clinical diagnosis: Anal pruritus without lesions of skin. Histological diagnosis: Chronic productive dermatitis (almost to the point of kraurosis). Features: Marked sclerosis of the fibrous connective tissue of the corium extending up into the papillae and surrounding the bloodvessels. Stain: Van Gieson.

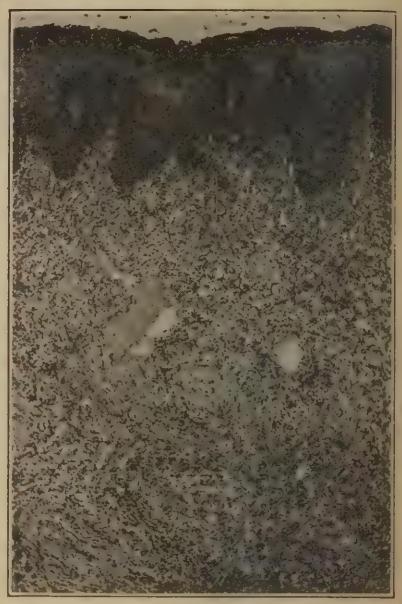

Fig. 5

Fig. 5.—Clinical diagnosis: An acute exacerbation of a pruritus ani of short duration. Histological diagnosis: Subacute exudative dermatitis of infective origin on a basis of chronic productive dermatitis. Features: Marked pigmentation of the epidermal layers; dilatation of the lymph spaces; diffuse cellular infiltration of corium, particularly intense subepithelially; some vascular dilatation; general edema of the tissue. Stain: Hematoxylin and eosin.

Fig. 6.—Bacteria found in the epidermal tissue in a case of pruritis ani.

cellular infiltration is not perivascular and hence, we may conclude the causative factor is not a blood borne toxin. There is also noted in some cases an increased pigment in the stratum granulosum with occasional deposit of pigment in the corium due, perhaps, to diapedesis of the red blood cells.

The pathological diagnosis of such a section is that it is significant of a chronic productive inflammation probably of traumatic origin. The process is essentially a chronic one, although in some cases an acute exacerbation may be found superimposed upon this chronic productive dermatitis. In general the process can be said to vary in degree in direct proportion to its chronicity.

3. We now come to that class of cases in which bacterial invasion is evident. Clinically it may be stated that in all these cases a solution of continuity in the overlying epidermis has occurred through the agency of one or more of the mechanical forces. In other words, in those cases lesions of the skin are present.

In such cases we not only see that conditions due to nondesquamation of hyperplastic epithelial cells known as hyperkeratosis, but also a marked hyperplasia of the rete cells with intracellular edema (Fig. 5) tending toward vesiculation and hypertrophy and projection downwards of the interpapillary processes. The conenctive tissue element of the corium is decidedly increased. We also note a marked subepithelial cellular infiltration in which the polymorphonuclear element is predominant, and some red blood cell diapedesis. There is marked dilatation of the lymph spaces, some vascular dilatation, and a general edema of the tissue. Sections of this type of case occasionally show upon Gram-Weigert stains scattered clumps of bacteria *in situ* in the upper layers of the tissues. It must be remembered that we have as yet no satisfactory methods of staining tissues to show gram negative microorganisms; hence, we cannot definitely say that such organisms as Bacillus coli are not found.

Despite great care in the selection of cases, the obtaining of specimens and the staining bacteria were found in only seventy-four out of some 1,700 sections examined. This of course must not be construed as being indicative of the absence of bacteria in all but the seventy-four cases. All that it can logically be assumed to signify is the success of the staining methods used in these instances.

Fig. 6 shows a section in which I have been able to demonstrate their presence. In all the specimens showing organisms present, said organism was, morphologically, a staphylococcus, and this was substantiated on culture in each case. In no case did their invasion appear to reach further than halfway to the basement membrane of the epidermis. Likewise, in each case there was an evident break in the surface epidermis or a distinct cystolysis of the superficial layers. There was not a single instance in which bacilli coli or the streptococcus fecalis was demonstrated in the tissues by staining methods. I have been able to demonstrate bacilli coli by cultural methods. These are described elsewhere.

The conclusion naturally follows that where the epidermis is injured by traumatism or maceration an invasion of bacteria may occur. This invasion in the cases studied is moderate and limited, due either to the resistance of the epidermal cells or to the low virulence of the invading organism.

The picture is that of an acute or subacute exudative dermatitis in some cases of mechanical and, in other cases, of infective causation. The cellular infiltration in these cases can be demonstrated to be particularly abundant in the papillæ around the end bulbs of Meissner (Fig. 1).

As an end result, lichenification and kraurosis result in both these types.

The usual sequence of pathological events in these

cases is, therefore, first, a condition of normal tissue or normal tissue plus the inciting lesion; second, a chronic productive dermatitis of traumatic origin, or in some cases an acute or subacute exudative dermatitis of infective origin which may later in both cases progress to that atrophic dermal condition known as kraurosis.

The foregoing are the essential pathological findings, but it must be mentioned for the sake of completeness that within the pruritic zone there also may occur, in some cases, various associated pathological conditions, which, though not a part of the pathological process of the disease, may contribute some features to it or in some cases furnish an actual inciting agent. As such may be mentioned condylomata, prolapsed hemorrhoids, fistulæ, ulcers in the terminal portion of the anal canal or between the two sphincters, small sinuses burrowing from the anal pockets, and the presence in some cases of parasites, such as pediculi, scabies, pinworms or thread worms and sometimes fungi.

Hypertrichosis: A Serious But Much Neglected Subject

WALTER WELLER, M.D.,
New York

INTRODUCTION

Two impelling motives caused me to select this subject for discussion. First, during the year 1919 I was requested by a friend to interest myself and see what could be done for his three daughters. Their ages were eighteen, twenty, and twenty-two years, respectively. Each one had become melancholy and morose as the result of a severe inherited condition of hypertrichosis of the face. I consulted various medical friends, and their joint advice amounted to the continued use of depilatories, shaving, and tweezing. A few dermatologists suggested electrolysis, but did not themselves do this work. For two years these and other suggestions were tried, only to end in failure and disappointment. I realized that with all the skill and science of the medical profession such a socalled simple thing as hypertrichosis was beyond their reach.

Secondly, in 1921, my attention was called to an article by Benjamin Reiley (1) describing his observations of the work done in hypertrichosis in Cornell Medical College by Albert C. Geyser. In the Academy of Medicine I found many of Geyser's writings concerning this anomaly. During 1921, these three sisters were treated by Dr. Albert C. Geyser. It required only six months to eradicate completely every trace of superfluous hair, and their faces have been absolutely clean and free from every blemish for two and a half years. I have every reason, therefore, to consider that the results are permanent. Two of these sisters have since married. I doubt whether that could have been consummated previous to the hair removal. This is my second reason for calling the attention of the medical profession to such an apparently insignificant disfigurement as hypertrichosis.

CAUSES

There is no doubt concerning the truth of the statement made by several competent observers that hypertrichosis or superfluous hair is on the increase. As far as my personal experience goes, I would say that there are two primary causes, viz., heredity and some internal gland derangement.

Heredity is easily understood, while the internal gland derangement is more difficult to grasp. The essential difference between these two causes is found in the fact that the hereditary type manifests itself during early or almost infantile life, while the glandular variety makes its appearance either about the time of puberty or at the menopause. We might add a third cause, namely, a combination of heredity and internal gland derangement.

There is, of course, little or no difference between these causes from a physiological or pathological point of view. There is, however, a marked difference in the behavior of these classes under therapeutic treatment. The first or hereditary cases respond quickly and permanently to modern therapeutic measures. When we are dealing with a derangement of the internal secretions, we are not able to remove the cause. We may remove the hairs but there is always the possibility of a regrowth. Although experience has shown that when the hair papillæ are thoroughly atrophied, sooner or later even these patients can be assured of a permanent eradication of this unsightly growth. As might be expected the foregoing remarks apply with an even greater degree to mixed cases.

USE OF COSMETICS

The reason for the general increase of hypertrichosis is not difficult to trace. The almost universal use of cosmetics, rouge, powders and lipsticks, has led to the more close inspection of the face for blemishes. As soon as a few fine hairs are discovered, they are promptly tweezed out. Each hair so tweezed strengthens the hair papilla, which cannot be removed, to the production of a more vigorous growth. Sooner or later the young miss makes use of the

various depilatories which is equivalent to shaving. All of the fine hairs so removed take on active growth.

Another method which cannot be condemned too strongly is the application of shoemakers' wax. This method of removing the hairs not only fails to affect the hair papilla but it tears off or out the individual hairs below the skin surface. When the hairs have attained even a moderate growth, the hair follicle becomes occluded after such wholesale tearing out from the general skin irritation. As a result the new hair fails to find the former exit and remains buried beneath the surface of the skin. Such a hair becomes practically a foreign body, it forms a pimple and festers its way out. When this shoemakers' wax is used in the axillary region the development of large abscesses is not uncommon.

The present day tendency of overbeautifying the complexion, then, is the direct cause of the noticeable increase in facial hypertrichosis.

TREATMENT

All attempts at removal with the razor, wonderstone or pumice depilatories, shoemakers' wax, etc., ought to be condemned. At best they are only a makeshift and defeat the very object sought. Electrolysis is too tedious, painful, and uncertain. The x ray, as originally discovered by Röntgen and afterward advocated by Schiff and Freud of Vienna, has now been completely abandoned as too dangerous, on account of its many and varied wave lengths.

Albert C. Geyser, formerly of Fordham and Cornell Universities, devised a method that is at once safe, sure and permanent. With this method only the shortest wave lengths are selected by means of a magnetic wave selector. I have had the unusual opportunity and privilege of observing upward of one thousand consecutive cases treated with this homogeneous wave length.

As a general proposition a certain area of the face or body is exposed once every two weeks. About three to five exposures cause the hair shafts to become loosened from the papilla. If after three more such exposures a biopsy is made, the papilla is not only atrophied but as a rule completely absorbed. From such a papilla it is of course impossible ever again to grow a hair.

Perhaps the most interesting point about this treatment is the fact that in upward of ten thousand applications, which came under my personal observation during the last year, there was not a single untoward effect upon the skin so treated. On the contrary, in all cases which had previously been exposed to the old time x ray treatment with the usual wrinkling and drying of the skin, became practically normal in a few weeks' time.

In conclusion, I would urge the general adoption of this method in all cases of hypertrichosis. The medical profession as a whole has looked rather too lightly upon this anomaly, but to the young woman afflicted with an overgrowth of hair, especially upon the face, this is a serious matter. She deserves the deepest sympathy and the best skill the medical profession can offer.

Insulin in Furunculosis

JOSEPH BIEBER, M.D.,
New York

Recently, while treating a case of persistent furunculosis over the entire body, I decided to use insulin, because the patient had a high normal blood sugar. The result was so gratifying that I think the case worthy of reporting.

Case.—J. B., aged forty, had suffered from precordial pain for several weeks. He was advised to take diathermy treatments, for which it was necessary to shave the hair off the chest. Several days later there developed at the site of the shaving a few hair follicle infections which coalesced and soon formed larger furuncules. These were opened and drained but in a few days the entire body was covered with over one hundred small abscesses, many of which required incision and drainage. The patient was very uncomfortable, and to say the least, was in an extremely miserable condition. Culture of the pus showed a staphylococcus aureus and an autogenous vaccine was made. The urine examination was negative. Since the condition was becoming progressively worse and although the urine was negative, it was decided to do a blood sugar test, as the patient appeared to be a potential diabetic, being stout and nervous. The blood sugar was 140 mg. which, while within normal limits, might be called a high normal. It was decided to use insulin and two units were given daily for four days. The furuncles began to clear on the second day of the treatment, and disappeared entirely in four days, almost like magic. There has been no recurrence and the patient is comfortable again. The rapid disappearance of the furuncles after the second injection was remarkable.

This case proves the value of insulin in cases of furunculosis where there is hyperglycemia or even a high normal sugar content of the blood. Insulin should never be given in these cases unless a blood sugar test has been taken, otherwise disastrous results may follow its indiscriminate use in furunculosis. However, in proper hands, and with accurate blood sugar readings, insulin is of distinct value in cases of furunculosis and should be tried in every case.

The Serological Diagnosis of Syphilis

ROBERT A. KILDUFFE, A.M., M.D.,

Los Angeles, Cal.

Of all diseases syphilis is the most protean in its manifestations and a tremendous responsibility therefore rests upon those directly or indirectly concerned with its recognition and treatment. There are few conditions presenting, as an aftermath of an erroneous diagnosis, more farreaching consequences; none requiring more skilled powers of observation and deduction, more acumen in the interpretation of the phenomena observed. Whether syphilis should be relegated to the hands of those especially trained and particularly adept in the management of this disease may be a matter of debate; that it ever will be is a dubious assumption. Probably the larger proportion of cases will be seen by the practitioner at large.

Prior to the application by Wassermann in 1906 of the complement fixation reaction to the diagnosis of syphilis, the recognition of the infection was contingent upon: 1, a careful and painstaking history carried, if need be, to the point of crossexamination; 2, a thorough, minute, and painstaking physical examination; 3, when these were indefinite, the employment of the socalled therapeutic test in which the syphilitic character of the lesions was held to be established if improvement occurred under the use of antiluetic remedies.

The introduction of the Wassermann test can safely be said to have had a pronounced effect upon the clinical study of syphilis in that, to some extent more or less marked in accordance with varied circumstances, the test was made to take the place of both history and physical examination; and it is undoubtedly true that in a definite proportion of cases the diagnosis of syphilis or the assumption of its absence has rested entirely upon the results of a single, isolated serological examination.

The natural result has been the production of situations tending to cast discredit upon the test and its performers with the subsequent expression of mutual recriminations between clinician and serologist. An unfortunate concomitant of this situation has been the tendency of each to foregather with his kind and for both to overlook the fact that only by the cooperation of both can the best results be obtained for the patient, in whose interests, after all, both are working.

Instead of each side having as its favorite "indoor sport" the pronouncement of a solemn indictment upon the other; instead of the clinician expressing in measured tones the necessity for the serologist to "realize the responsibility that is his for a false report" (1) or emphasizing that "they—the serologists—should get together and perfect their technic in such a manner that we may with safety accept their reports on their face value"; instead of the serologist giving vent to muttered and sometimes violent criticism of the clinician in regard to use of the test, or making pleas that he temper his demands upon it with at least an elementary understanding of the principles upon which the reaction is based, is it not time that the diagnosis of syphilis rest, not always upon clinical observations alone, nor upon laboratory investigations alone, but upon the combined and pooled knowledge of clinician and serologist working in unison?

The important thing is the diagnosis, and a diagnosis in any condition—and particularly is this true of syphilis—depends, not upon any one factor, but upon the combined significance, upon the *sum total* of all the observations made.

There are few conditions in which the powers of clinical observation must be more keenly developed and in which the results may be more fallacious than in syphilis. A chancre may be far from typical in appearance; a suspicious rash entirely nonluetic in origin; and it must be remembered that mercury, the iodides, and even the arsenicals have therapeutic values in conditions other than syphilis. Under such conditions even the most thorough of examinations, the most careful of histories, may result in inconclusive evidence; naturally, therefore, the advent of the Wassermann test and the dark field illuminator was received with avidity.

But it will never be possible for any method of laboratory examination to relieve the clinician of the necessity for anything other than the collection of the specimen. Unfortunately, the tendency has been to throw the entire burden of proof upon the laboratory, overlooking the fact that the Wassermann test and the dark field may be negative in a definite proportion of cases. Nor does the reason for this, par-

ticularly in the case of the dark field, always lie in the laboratory.

If it is important and essential to have a knowledge of the various laboratory procedures which are capable of transmitting informative data in various pathological conditions, it is equally important and even more essential to have, also, a knowledge of their limitations and their fallacies. Every laboratory examination must be interpreted, and the complement fixation test is no exception—it will never be automatic.

For the diagnosis of syphilis there are several desiderata:

1. There should be something more than a perfunctory history. A denial of infection is of little value. Not only must questions be carefully devised, but any possible "leads" uncovered by the entire history should be tactfully followed up.

2. The physical examination should include a definite attempt to note the presence or absence of findings of value in connection with lues: scars, adenopathy, reflexes and the like should all be investigated.

3. Not until now should the laboratory enter the field by way of the dark field or the Wassermann test.

4. Finally, when all the data are thus gathered, both serologist and clinician should cooperate in their proper evaluation and especially is this true when the various findings are puzzling or indefinite.

Much has been written and still more said concerning who shall be the interpreter. In the long run it is not the honor nor the pride of the clinician or the serologist which is at stake; something more vital, farreaching, and important than such minor personal considerations is at issue—the welfare of the patient.

Few there are—clinician or serologist—who are willing to assume responsibility for the aftermath of a missed diagnosis of syphilis, missed because of lack of skill or care; fewer still to carry the burden of a false diagnosis of syphilis where none exists with its sequelæ of unnecessary physical and mental suffering. The responsibility should be equally divided and equally shared. What, therefore, should the serologist demand of the clinician in the way of cooperation?

First: That he be sufficiently acquainted with the mechanism and rationale of the laboratory methods of examination to assure the proper collection of specimens for examination, for many and various are the factors thus concerned in influencing the results of tests made.

Probably every serologist has had the experience of being asked to make a dark field examination on a lesion which has been energetically treated with salves, powders, washes, and even the cautery, and the chances are that the clinician deeming such a lesion suitable for dark field examination is quite likely to decide against the possibility of syphilis on the basis of a negative finding secured under such circumstances. Every serologist has, at times, received specimens of blood in every conceivable sort of bottle, at times even on slides; hemolyzed by alcohol used in sterilizing the syringe with which the specimen was taken; in containers of all sizes and shapes, neither sterile nor absolutely clean or washed with various solutions apt to render the specimen anticomplementary. Consistent and reliable results under these conditions are quite difficult.

Second: That the clinician realize that when the serologist transmits a positive or negative report he implies by that statement, not that the one patient has syphilis and the other not, but simply that the blood examined did or did not contain a substance capable of fixing complement in the presence of a syphilitic antigen *at the time of examination.*

The meaning, significance, and interpretation of such a reaction is a matter wholly beyond and outside the fact of its occurrence, into the estimation of which many factors enter, among which are: a, the other collected data relative to the case—for which the clinician is responsible; b, the suitability of the specimen for such examination—with which both clinician and serologist are concerned; and c, the delicacy, reliability, and dependability of the technic used in making the examination—for which the serologist must accept responsibility.

Third: That if the clinician desires to saddle upon the serologist the burden of responsibility for the interpretation of the complement fixation test, he appreciate the necessity for giving the serologist the facilities extended to any other consultant in obtaining such additional clinical and historical data as may be needed.

Fourth: That if the clinician assumes the responsibility for the interpretation of the test, he also assume the responsibility for acquiring sufficient familiarity with all the details and factors influencing the result; that he be perfectly familiar with the limitations of the test and competent properly to evaluate its results.

These requirements being fulfilled, there will be no queries as to why a specimen was anticomplementary and what that means; fewer debates as to how a complement fixation test could be negative when the patient undoubtedly has syphilis, and vice versa; and less discontent on the part of both serologist and clinician anent the faults of the other.

On the other hand, what should the clinician demand of the serologist?

First: That he should *be* a serologist, thoroughly trained and grounded in the elements of his specialty and not merely a manipulative expert; that he should be thoroughly competent, not only to evaluate the results of the studies of others, but to conduct informative investigations of his own.

Second: That he should be a continual student in his own and related specialties.

Third: That he should take an active part in the constant endeavors to throw light upon the subject of the serological diagnosis of syphilis.

Fourth: That, when called upon, he should have had sufficient clinical experience correctly to correlate and interpret the combined clinical and laboratory data pertaining to the particular case.

Fifth: That he should not be unalterably wedded to one method alone but willing and eager to investigate the merits of new proposals and, if these are substantiated, to adopt them in his own work in part or entire as occasion demands.

Sixth: That he should be satisfied in so far as is possible of the reliability and delicacy of the method he prefers on the basis of experience; willing and

able to interpret the results, and equally willing to substitute another for it when he shall have been shown that it is superior.

Granting a cooperative response to such requirements; granting a realization on the one hand that the laboratory examination may be vastly influenced by circumstances surrounding the collection of the specimen; granting that the complement fixation test may be negative in the presence of syphilis and, also, with the usual methods in vogue, occasionally positive in its absence; granting that the results of the laboratory examination should never be allowed to overshadow the clinical data obtained; granting the essential importance of gathering such clinical data with which the laboratory data may be correlated; granting the combined and united efforts of both serologist and clinician, results of incalculable benefit to all concerned are bound to follow, and in such cooperation lies the greatest hope of the eventual conquest of the spirocheta and its admiring circle of lymphocytic satellites.

Vasovesiculitis Simulating Acute Appendicitis

U. G. DAILEY, M.D.,

Attending Surgeon, Provident Hospital

And W. S. GRANT, M.D.

Attending Urologist, Provident Hospital, Assistant Clinical Instructor in Dermatology, Northwestern University Medical School

Chicago

The possibility of mistaking acute seminal vesiculitis for acute appendicitis is fairly well known, especially among genitourinary practitioners; yet few reports on the subject are found in general surgical literature. Hence it would seem justifiable to call renewed attention to the subject and to report the appended examples.

Case I.—In August, 1916, one of us was called to a neighboring town to see a patient in a hospital who wished the diagnosis of appendicitis confirmed before operation by one of the local staff. He had been sent to the hospital by his family physician as a case of acute appendicitis. This diagnosis had been agreed with by the hospital surgeon, and preparations were being made for immediate operation. The history obtained at the time, briefly was as follows: The man, a chauffeur, married, aged twenty-eight years, had been at his usual work without complaint until the afternoon of the previous day when he began to experience rightsided abdominal pain, which came on gradually, but with increasing severity. He continued at his work until his time for leaving, 6 p. m. By 9 p. m. the pain was severe enough for his wife to insist upon calling a physician who arrived at 10 p. m. and, after an examination, made a diagnosis of acute appendicitis. He (the patient) thought his temperature was rather high, and stated that he had been nauseated, but had not vomited. My examination revealed distinct tenderness in the right lower abdominal quadrant somewhat below McBurney's point. In fact, pursuing the examination further, the greatest tenderness was found to be in the right half of the hypogastrium. The cord, epididymis and testes were investigated and a rectal examination made. The vesicles were distinctly tender, and upon milking the urethra a small drop was made to appear at the meatus. The patient then admitted that he was at the time under the treatment of another physician for gonorrhea.

Case II.—T. S., aged thirty-one years, consulted us July 12, 1923, with a history of repeated attacks of urethritis. The smear showed many intracellular and extracellular gonococci. The glass test showed pus in both the urines, but most abundant in the first. The prostate was not enlarged or tender, and the vesicles were not palpable. His general health seemed perfect, and he had no other complaints. The Wassermann was negative and the colloidal gold test two plus. The usual weak irrigations were made on the 12th and the 13th. On the 14th he presented himself at the office complaining of pain in the right iliac region. The pulse was 96, the temperature 99.4°. There was some nausea. A cathartic had been taken, but usually he was not constipated. As this patient was under our treatment for Neisserian infection, the question of the possibility of acute appendicitis did not seriously arise, but there were so many points suggestive of the latter that conceivably a superficial diagnostician, in the absence of the history, might fall into error.

A description of the findings and the further course in this case is perhaps interesting. Examination revealed the following: There was a point of maximum tenderness located on a line drawn from McBurney's point to the spine of the os pubis and one and a half inches above the latter. The right spermatic cord was slightly enlarged and tender. The rectum was hot and the right vesicle tender. There were no subjective urinary symptoms, but both glasses contained coarse flocculi and *tripperfäden*. The urine was acid, specific gravity 1,023, color golden yellow, trace of albumin, but aside from pus and epithelial cells there was nothing else of interest.

In describing the pain he stated that it came on gradually, seemed deep in the pelvis, and decidedly accentuated on deep breathing. He felt very feverish, his appetite was impaired. Balsams and alka-

lies and bland diet were ordered, injections omitted, and he was advised to remain off his feet. He nevertheless worked that night, his occupation of club-keeper permitting him some latitude, and he stated, when seen the next day at his room, that he was on his feet but little. Examination on the afternoon of July 15th confirmed the previous findings, but the pain was worse and the possibility of confusion with an atypical case of appendicitis was even greater. There was also pain posteriorly over the right kidney. The diagnosis of Neisserian deferentitis and vesiculitis was made with entire assurance, the outcome confirming it. He appeared at the office on the 17th with all of the symptoms on the wane.

Case III.—A man, twenty years of age, was admitted to the surgical service of Cook County Hospital with an examining room diagnosis of acute appendicitis. He complained of pain and tenderness in the right lower quadrant, of about ten hours' duration. The pain was first felt in the right iliac region and continued to be localized in this area, but was much more marked at the time of entrance to the hospital than at the onset. There was no chill or vomiting; some nausea was present. Gonorrhea was at first denied, but the patient subsequently admitted having had an acute attack three weeks previously, and that he had been treating himself for fear of exposure. Temperature was 101°, pulse 98, respiration 20. There was definite localized tenderness in the right lower quadrant, somewhat lower than McBurney's point, most marked along the course of the inguinal canal, and right rectus rigidity in the lower half. Testicle and epididymis showed no abnormal findings. No urethral discharge. Blood findings: hemoglobin, 90; leucocyte count, 11,500, with 80 per cent. polymorphonuclears. Urine, first glass cloudy; second glass hazy.

We had almost come to the conclusion that the case was one of acute appendicitis, but decided to make a rectal examination for the sake of completeness. This revealed a tender, enlarged and distended right seminal vesicle and a distinctly tender, palpable vas deferens. The prostate was also tender. With this additional evidence and admission of a previous gonorrhea, the diagnosis of acute seminal vesiculitis and deferentitis seemed more likely, but for fear of probable error, Dr. R. T. Vaughan, night warden and member of the surgical staff, was called to see the patient. After an examination he concurred in the diagnosis of acute seminal vesiculitis, and commented upon the possibility of confusion with acute appendicitis unless careful examinations were made.

This case emphasizes the value of rectal examinations especially in atypical or dubious cases of suspected appendicitis.

The number of cases cited might have been multiplied, but the three selected will serve to exemplify the point of this article.

COMMENT

Such men as Keyes (1) and Cabot (2) make no reference to the possibility of confusing vesiculitis and appendicitis. White and Martin (3) state that seminal vesiculitis has been mistaken for appendicitis and the symptoms may be identical. Of works on general medicine and surgery, John A. Lichty (4), in an extensive article on the differential diagnosis of acute appendicitis, does not mention seminal vesiculitis. Osler and McCrae (5) make no reference to this source of error. Herbert French (6) fails to list seminal vesiculitis among the causes of pain in the right iliac region. The late J. B. Murphy (7) states that "acute infections of the vas are to be thought of." Guiteras discusses the remote manifestations of inflammation of vasa and vesicles in the following words: "Pain occurs principally in the perineum, the groin and the glans penis. It may also, though less often, be noticed in the testes, sacroiliac region, the back, deep in the pelvis, thighs, and loin. It may be connected with urination or defecation, or may be independent. Pain in the perineum is sometimes described." But he ignores the occurrence of cases such as we cite.

The current literature of recent years contains occasional allusions to the fact that abdominal symptoms may occur with seminal vesiculitis. E. M. White (8) says: "The abdominal symptoms are due to the peritoneal investment and may simulate acute appendicitis, ureteritis, ureteral colic or stone, and due to the close proximity to the bladder, abscess formations with perforations into this viscus have been reported, also rupture into the peritoneal cavity by way of the rectovesical cul de sac. Pyemia has been known to follow a septic phlebitis of the adjacent venous plexuses. Pelvic cellulitis with marked suppuration is possible. Dull, persistent, suprapubic pain, constant pains in the lower lateral quadrants of the abdomen with a chronic urethral discharge should always suggest vesicle trouble. All the author's cases had one or more abdominal symptoms.

On the other hand, so experienced an authority as A. L. Wolbarst (9), in a recent contribution on the diagnosis and surgical treatment of seminal vesiculitis overlooks this important diagnostic snag.

CONCLUSIONS

The point of the present communication is that all practitioners who are called upon to decide the presence or absence of appendicitis in the male, should make certain, particularly if the suspected case is somewhat atypical, that the seat of the trouble is not in the vasa and vesicles. All that is necessary is to keep in mind the possibility, and a digital rectal examination will make clear the differentiation.

The Prostates We Should Not Massage*

P. S. PELOUZE, M.D.,
Philadelphia,

Owing to the ease with which the diagnosis of chronic follicular prostatitis can be established we have been, and still are, passing through a phase of rather indiscriminate prostatic onslaughts. Too little care has been taken in determining whether such treatments promised benefit or would be productive of harm to the patient. Discontinuing the local attack upon the gland when trouble had eventuated, instead of foreseeing such a possibility, has been instrumental in discrediting this extremely valuable procedure in many quarters and has been productive of complications of much gravity in not a few patients.

The dividing line between the prostates that are benefited and those that are harmed by any kind of manipulative treatment is not always easy to determine. It is, however, of the greatest importance that they be differentiated from one another. The recognition of those that should not be massaged often taxes one's clinical judgment to its utmost; doubts often arise and when they do a good rule to follow is, do not massage.

There are certain groups in which doubts should not arise and in which judgment should dictate the safest course. On the other hand, certain borderline groups are prone to mislead, for which reason an effort will be made to discuss them briefly.

THE ACUTELY INFLAMED PROSTATE

It seems hardly necessary to sound a note of warning against digitally disturbing such an organ, but it does not always escape insult. Such prostates are usually hot, swollen, throbbing and decidedly tender. Their massage is a blunder that may cause abscess formation by breaking down the barriers to infection that nature is trying to form. Also, it is conceivable that even greater damage could be done by causing a systemic invasion by the infecting organism.

THE TENDER PROSTATE

Proper massage of the chronically inflamed prostate is uncomfortable but it is not acutely painful. The general rule can be made that the very tender prostate, if massaged at all, should be massaged with the utmost gentleness and care. It is a borderline gland which should arouse suspicion.

Under this heading might be included a type of infected prostate, the diagnosis of which can be obtained only from the history, as it may be perfectly normal to palpation. The history of these patients is that suddenly, either with or without vesical discomfort, there appears a cloudy urine, at times followed by a urethral discharge. The condition is apparently due to the rupture of small submucous pus pockets, though there is seldom any acute pain. These patients commonly give no history of previous venereal disease and are usually free from gonococci. The seizures are often accompanied by a frequency of urination, lasting several days and then subsiding. Recurrences are common. Palpation of these prostates shows nothing diagnostic, though there is often great tenderness if gentle pressure is made upon the midline in the region of the vesical outlet. While these prostates are loaded with pus, massage should be withheld until the tenderness is no longer present, and discontinued if it causes prolonged discomfort.

THE CALCULOUS PROSTATE

The presence of calculi in the prostate is usually discovered by the transmission of a clicking or crepitating sensation to the finger. Calculi of varying sizes may, however, be present in the gland and not be discovered. This probably accounts for a small number of the prostates that are not improved by any form of treatment. Stones of any considerable size will generally cast an x ray shadow. Massage of these glands does no harm, as a rule, but it rarely does any good except where there are distinct symptoms of toxic absorption from the prostatic acini.

THE NODULAR PROSTATE

Nodules of any kind in the prostatic substance should be viewed with great suspicion and massage withheld until they are proved not to be tuberculous or malignant.

Theoretically, interstitial inflammation of the prostate can cause marked nodulation of the gland and, from an academic viewpoint, such must be admitted to be the case, but from a practical, clinical view this possibility had best be forgotten.

It is not enough to consider that only hard nodules are tuberculous or malignant. The acute tuberculous focus is not hard and in the markedly nodulated tuberculous prostate soft swellings are common. Massage of the tuberculous prostate is usually followed by marked activity in distant organs, if not by a generalized miliary tuberculosis and death. Also, massage is poor treatment for malignancy. The proportion of such prostates that are subjected to massage is far greater than it should be.

THE NONRESPONDING PROSTATE

Under this heading may be grouped that considerable number of patients in whom there seems to be clinically no contraindication to massage but who either grow worse or do not improve during the time it is carried out. It can be safely said that if the local symptoms of these patients are not improved or banished after six weeks of treatment a pathological condition exists other than a follicular prostatitis. By this it is not to be inferred that one can render such glands free from pus in that time but that there should be a subsidence of subjective symptoms and an improvement in objective. These patients should be given a careful cystourethroscopic study. In most of these prostatic urethræ will be found the lymphocystic bodies that I have described as an evidence of systemic tuberculosis (1).

Whether or not you accept my statement as to their etiology, the fact remains that no amount of massage will clear up the prostate while these bodies are present. Whereas, an antituberculous régime will usually, in the entire absence of urethral treat-

*From the Department of Urology, University Hospital.

ment, cause these lesions to disappear spontaneously after which the prostate usually responds to massage. Furthermore, as I have reported four cases of very active tuberculous lesions following prolonged courses of massage in such cases, there is an even more important reason why systematic massage should be withheld during the persistance of these lymphocystic urethral lesions.

In some of these nonresponding cases many very large prostatic openings are seen in the posterior urethra. Some of these are openings to old played out abscess cavities whose walls are so rigid they cannot collapse. These patients may be benefitted by the occasional drainage afforded by massage but they cannot be cured by the procedure. McCarthy has attributed the large, scarred prostatic openings to a played out tuberculosis. In such cases massage is decidedly contraindicated by the possibility of reactivating dormant tuberculous foci. As a matter of fact, it would really be wise to precede massage in all chronic prostatic conditions by a cystourethroscopic study and thus avoid such unfortunate experiences.

PROSTATITIS IN TUBERCULOUS PATIENTS

Landis has repeatedly insisted that a distinct hazard is entailed in the massaging of prostates in patients known to have tuberculosis elsewhere in the body. He has seen two cases of acute miliary tuberculosis follow such treatments. These, added to those mentioned in the preceding section of this paper, should certainly make one cautious where tuberculosis is known to exist.

Perhaps it is too sweeping to say that in tuberculous subjects prostates should never be massaged, but certainly there should be something more important than the presence of pus in the prostatic secretion to tempt one to do so. It is justifiable in such patients who present no evidences of prostatic tuberculosis to carry out very gentle prostatic strokings in the presence of chronic gonorrheal prostatitis or where definite systemic symptoms are proved to be due to the absorption of prostatic pus. Such manipulations should never be done for longer periods than necessary to accomplish the object sought. The presence of nongonorrheal pus in their prostatic secretions should be disregarded.

THE FIBROID AND HYPERTROPHIC PROSTATES

The former are small and very dense to palpation and are occasionally accompanied by referred pains in the penis, perineum, rectum or inguinal regions, which is not relieved by massage. The latter are recognized by their size and consistency and accompanying vesical symptoms. In them massage does neither good nor harm.

THE AIM OF MASSAGE

It should never be forgotten that prostatic massage is applied for the cure of disease; that the tissue directly attacked is the seat of disease; that no lesion in the body is best cured by roughness and that this organ offers no exception. Our aim is threefold and is only reached by gentleness. We desire to promote drainage in a poorly draining organ, to improve its circulation and to stimulate its musculature. Bruising cannot accomplish any of these and may do great injury .

The Rôle of the Renal Nerves in the Process of Urinary Excretion

JONAS KAGAN, M.D.,
Boston,
Formerly Head of the Laboratory at the Surgical University Clinic of Geneva, Switzerland

The rôle of the renal nerves in the process of urinary secretion is far from clear. Although their vasomotor action is well defined, no special secretory nerves have been found. On the other hand Carrel in 1908-1910 showed that one of his experimental animals lived two years after the transplantation of both its kidneys. At autopsy it was seen that the kidneys remained entirely normal, although this transplantation demanded a complete section of the nerves, thereby interrupting the nervous connection. Unfortunately Carrel does not mention the functional changes following the operation; at that time such functional investigations were not the vogue.

In the American literature (1) much discussion of this question took place. Asher and Pearce several years ago believed that they had found secretory fibres in the pneumogastric nerve. Later, however, Pearce (2) doubted this conclusion, for he could not prove an increase in oxygen consumption, which is the only index of the augmented cellular activity. Marshall and Kolls (3) show that in the process of diuresis the section of the splanchnic nerve and the changes in the rate of the blood flow through the kidney vessels give the same result. Similar results are obtained by compression of renal arteries. The excretion of urine depends more on the quantity of the blood which passes through the renal vessels than on the height of the blood pressure in the kidney. As a consequence of cutting the splanchnic nerve, there is dilatation of the vessels with an increase in the quantity of the urine. These authorities also assert that there is a difference in the excretion of sulphates from other salts (chlorides). The excretion of the latter depends only on the quality and quantity of the blood which passes through the kidney. If the splanchnic nerve of one kidney is cut, that kidney will excrete more sodium chloride than the other. But the excretion of sulphates in both

kidneys is equal, because this depends on the activity of the kidney cells. In accordance with this fact the pressure on the renal artery causes diminution of the excretion of the chlorides, but does not change those of the sulphates.

O. Pico (4) discussing Marshall and Kolls's articles (3) reported his experiments. Pico found that the change in the function of the kidney occurring after the section of the renal nerve was mostly an increased excretion of chlorides. It follows even in the absence of polyuria.

Ambard and Papin (5) recently devoted to this problem a part of the articles in their new review, *Archives des maladies des reins et des organes génitourinaires.* In recent years Papin's procedure for relief of kidney pain was to sever the renal nerve in the hilus. He employed this operation only in cases of nephritis accompanied by pain, or in mild cases of hydronephrosis with pain, or in all general cases of nephralgia or kidney neuralgia of uncertain origin. He supposes that this operation is more rational than the radical operation of nephrectomy or the insufficient nephrotomy, decapsulation of the kidney or nephropexy (6). In six[1] such operations performed by Papin the results were successful in stopping pain. At the same time Ambard used these operations for observing the secretory changes in the operated kidneys. Ambard maintains that the phenomena following immediately after operation must be differentiated from those following later. The effect of postoperative infection must be borne in mind. There is no doubt that polyuria follows the section of renal nerves. It is confirmed also by the experiments of P. Jungman and E. Meyer. They performed the following experiment: cutting the splanchnic nerve of the left kidney and collecting the urine of both kidneys by means of a catheter at certain intervals. The results were as follows:

		Right Kidney				*Left Kidney*				*Urinary Bladder*			
		one half hour				*one half hour*							
		I	II	III	IV	I	II	III	IV	I	II	III	IV
Amount of urine		24c.c.	91c.c.	44	28	125c.c.	230	128	86	0	109c.c.	73c.c.	0
Urea	*per mille*	2.2	1.5	2	2.6	2.4	1.3	2.1	2.5	—	1.5	2	—
NaCl	*per mille*	1.7	1	2	2.2	2.3	1.3	2.2	2.6	—	1.3	1.7	—

Time	*Right Kidney* *Amount of urine*	*NaCl*	*Left Kidney* *Amount of urine*	*NaCl per mille*
4 hrs. 30 min. to 4 hrs. 45 min.	0.5 litre	trace	0.7 litre	0.6
			section of the splanchnic	
4 hrs. 45 min. to 5 hrs. 15 min.	0.9 litre	trace	2.2 litre	9.4
5 hrs. 15 min to 5 hrs. 30 min.	0.6 litre	trace	1.25 litre	1.17
5 hrs. 30 min. to 5 hrs. 45 min.	0.8 litre	trace	1.6 litre	1.17
5 hrs. 45 min to 6 hrs.	1.3 litre	trace	1.6 litre	trace
6 hrs. to 6 hrs. 30 min.	1.0 litre	trace	2.3 litre	trace
6 hrs. 30 min. to 7 hrs.	3.0 litre	2.9 per mille	1.5 litre	trace

The marked polyuria, as shown in this table, is for a very short time. It lasts only for several hours, then there is practically no difference between the diuresis of the healthy kidney and the one operated upon. This fact which was observed also by other experimenters is attributed by Ambard to the subsequent infection. Such polyuria will persist at all times, during which the kidney parenchyma is irritated by the infection. If no infection followed the operation, diuresis becomes normal very soon. As confirmation of this fact, the author reported the result of his experiment with a dog. Ambard cut the nerves of the left kidney, the urine was collected every fifteen minutes. The results were as follows:

Right Kidney *Amount of Urine*	*Urea*	*Left Kidney (the operated)* *Amount of Urine*	*Urea*
15 c. c.	26 per mille	10 c. c.	30 per mille
22 c. c.	19 per mille	20 c. c.	20 per mille
35 c. c.	16 per mille	31 c. c.	17 per mille
38 c. c.	15 per mille	32 c. c.	17 per mille
28 c. c.	17 per mille	24 c. c.	18 per mille
20 c. c.	22 per mille	17 c. c.	24 per mille

As is shown by this table there is no marked difference in diuresis of either kidney. The same result was found by the investigations of patients operated on by Papin. Ambard reported one case among others of section of the right renal nerves in a patient (May, 1921) who was catheterized four months after the operation and the urine was collected every thirty minutes.

The urine found in the bladder was without doubt excreted by the right kidney (having the same concentration of urea). It is evident that after the section of the nerves on one side, both kidneys for a period of four months performed their functions equally well. This result demands an explanation. How is it possible that the kidney not having any connection with the nerve system, nevertheless several hours after the operation is not different in any way from the excretory function of the nonoperated kidney? Ambard asserts that the kidney being without nerves excretes the urine in the same amount as it excretes in normal conditions; but if it is irritated (by sudden cooling of the body), then the kidney function becomes insufficient. The section of the nerves which passes to the kidney certainly produces changes in the kidney function, but these changes appear only in special conditions, and can be demonstrated only artificially.

If on account of the operation the central stimulus becomes broken there remains, however, the influence produced by the organ itself. In normal conditions the direct irritation of the kidney itself possibly has the predominant rôle; hence there is no disturbance of the excretion of urine. Ambard confirms the fact that after unilateral section of the renal nerves the excretory function of this organ remains without marked disturbances for four months.

Will the kidneys retain their function indefinitely after operation? Do they possess the peculiarity that with its nerves destroyed, it remains, nevertheless, anatomically and functionally normal? Only further investigations will give a definite answer.

[1] After completing this article I found in the *Archives Franco-Belges de chirurgie* (July, 1923) a new paper from Papin where he gives the number of such operations as twenty-seven for enervation of the kidney.

Hypertrophy of the Prostate in the Hands of the General Practitioner*

LOUIS NEUWELT, M.D.

New York

In order to obtain a clear understanding of the proper course to pursue, whether the treatment should be palliative or radical, it is well to review briefly the clinical picture of socalled hypertrophy of the prostate, which may be conveniently divided into three stages.

In the first stage, or premonitory period, the first symptom to be noticed is a slight difficulty in starting the flow of urine and a deficiency in the force of the urinary stream; there are also symptoms of irritation, such a frequency of urination, especially once or twice at night, or during the day after the ingestion of alcoholics, and nocturnal erections, occurring in spite of lessened sexual power. This stage need not necessarily progress to the second and third stages, but may rarely remain stationary for many years or even permanently.

The second stage, or insufficiency of the bladder, is characterized by a slow and gradual development of retention of urine, increased frequency of urination, a feeling of incomplete emptying of the bladder after urination and the presence of residual urine. This stage may also last an indefinite time, or it may advance to the third stage.

The third stage is the period of incontinence, in which the bladder becomes enormously distended, even up to the umbilicus, the desire to urinate recurs every five or ten minutes with the passage of only a few drops of urine, or incontinence results—complete retention with dribbling. As a result of the increasing back pressure on the ureters and kidneys, constitutional symptoms appear, especially in the old and feeble, such as anorexia, flatulence, constipation, dyspepsia, a brown and dry tongue, emaciation, slight evening rises of temperature and drowsiness—a true urosepsis, due to the absorption of toxic material from the urine and the retention of waste products owing to the insufficiency of the kidneys from back pressure.

To complete the picture, the complications are mentioned. Retention of urine occurs in nearly every case of prostatic hypertrophy and may be acute or chronic. The acute form is often due to chilling or wetting of the surface of the body and taking cold, the sudden congestion of the mucosa around the vesical orifice causing it to swell and occlude the opening entirely. Retention may also be due to spasmodic stricture which is a reflex from constipation or rectal scybala, or from acidity of the urine. Normal urination is generally partially restored by catheterization, but retention soon recurs and the patient enters the second stage. Chronic retention is due partly to the obstruction at the vesical outlet from the enlarged prostate and partly to atonicity of the bladder musculature. Cystitis is the most common complication, being favored by the residual urine and passive congestion; it often results from instrumentation or from the invasion of colon bacilli from the rectum. With suitable treatment it improves considerably, but it is rarely cleared up entirely. Vesical calculi are associated with cystitis, especially in untreated cases. Pyelitis and pyelonephritis cause urosepsis. Hematuria results from the varicosities of the venous plexus of the bladder from pressure. Epididymitis results from the frequent or constant use of the catheter.

At first, the prostatic condition is a purely local and mechanical disturbance of the bladder, but sooner or later the kidneys become damaged as a result of functioning against great pressure, with a consequent disturbance in the functions of all the vital organs. All the body tissues suffer from the toxemia produced by imperfect elimination. The kidneys are affected the most seriously, thereby reducing the reserve power required to overcome the effects of even the slightest operation. The cardiac muscular power is also reduced and the lungs become predisposed to infection. The prostatic always has a sword over his head hanging by a thread.

The periods of apparent remission are not due to actual improvement in the underlying pathology of obstructive nature, but are merely the result of lessened congestion or of the elimination of some irritant which produces the edema of and around the prostate. With the advance of age the hyperplasia of the prostate increases and consequently palliative measures should not be advocated for the purpose of delaying the operation, except possibly in the first stage. But even in this stage radical measures are indicated as soon as signs of progression become evident. Neither age or debility, of themselves, are essential contraindications to operation. However, patients seventy-five or eighty years old, had better be treated palliatively. Eventually, from the very nature of the disease, operation must be done. Death will result unless the urinary retention and infection of the urinary tract are relieved. Early operation is necessary to prevent infection of the kidneys and the deterioration of the patient's general condition. The prognosis of operation is much better if done upon a patient in good general health than when it is done several years later when he is worn out from suffering and handicapped by diseased kidneys. For hospital patients and those who are unwilling or unable to practise aseptic catheterization, an immediate operation is indicated. At the same time it should be remembered that catheterization does render a certain number of patients comfortable even in the presence of complete retention. An intelligent patient should have the situation explained to him and may be allowed to take his choice of palliative or operative treatment, but if the palliative treatment is chosen, the patient must be kept under supervision and if the catheter must be passed with increasing frequency, if the urethra becomes irritable and painful, and if the cystitis is no longer easily controlled by bladder irrigations, operation should be urged, as further delay of operation only imperils the patient's life

*Read at the Harlem Medical Association, December 5, 1923.

and lessens the chances of surgical procedures.

Since catheterism is bound to show ill effects in time, catheter life should be reserved for those cases in which there is some serious and permanent obstacle to operation, such as diabetes, advanced heart disease, arteriosclerosis, hemiplegia, carcinoma, or some other serious illness. Operative treatment or catheterism is indicated: 1. When the bladder has lost its power of complete emptying and the amount of residual urine measures three ounces or more; 2. when the patient's health is disturbed by the nocturia, which may occur even when the prostate feels small. If the residual urine amounts only to one half ounce, relief may be obtained by a carefully directed and hygienic life. Before advising treatment, we must determine whether or not serious damage has not already occurred. If the power of voluntary urination is lost, requiring frequent catheterization, or when catheterization is impossible or painful, permanent suprapubic drainage under local anesthesia is indicated.

Before advising a prostatectomy, we must bear in mind that the patient's reserve powers will be greatly taxed by the loss of blood, the absorption of necrotic material and a resulting strain upon the emunctories, and more or less sepsis. The reserve powers of the circulatory and excretory systems must be determined by ascertaining: 1. the reserve power of the heart, 2. the hemoglobin content of the blood, 3. the blood pressure, 4. the amount of urine passed in twenty-four hours and its specific gravity, and 5. the reserve power of the kidneys. If the hemoglobin content is lower than sixty per cent., prostatectomy is dangerous. Polyuria with a low specific gravity of the urine and a low urea content should arouse the suspicion of chronic interstitial nephritis. If the urea content of the urine is 1.5 per cent. the patient will probably withstand prostatectomy, and, other conditions being favorable, some patients will withstand prostatectomy even with one per cent. urea. The phenolsulphonephthalein test of renal function may also be used.

If these tests result unfavorably, the patient should be prepared so as to make him a suitable operative risk by relieving the pressure against which the kidneys must work, with the prostate left intact. This may be done either with an indwelling catheter, which should be tried first, or by suprapubic drainage. The latter is indicated: 1. if catheterization is impossible; 2. if the urethra is intolerable to an indwelling catheter; 3. if there is much urinary sepsis; and 4. if the period of drainage has to be prolonged. The latter period is usually ten to fourteen days, but it may be several months. If there is much residual urine or overflow incontinence, the evacuation of the bladder must be gradual so as to avoid uremia or hemorrhage from the bladder. This is done by catheterizing the patient every four hours, evacuating about twenty ounces each time until the bladder is emptied, when an indwelling catheter is maintained in the urethra, or the catheter, supplied with a plug, may be tied in the urethra and the plug removed every four hours. Uremia or bladder hemorrhage that follow a too rapid evacuation of the bladder may be relieved by filling up the bladder with a bland or mild antiseptic solution, like boric acid or normal saline solution.

If for any reason surgical measures are inapplicable, palliative measures may be tried. Hygienic measures must not be neglected in any case. In the prostatic, any excess reacts unfavorably on the pelvic organs by producing congestion, which must be avoided. Draughts and wet feet are dangerous. The clothing, especially the underwear and footgear must be suited to the weather. All excesses—physical, mental, sexual, dietetic or alcoholic—must be avoided. The diet should be light, bland and laxative, avoiding much meat. The emunctories should be kept active. The urine should be kept bland by the drinking of plenty of water. The bowels should be made to move at least once daily; straining at stool must be avoided. The urine should never be retained longer than three or four hours during the day. If nocturia is present, the urinal should be used in bed to prevent chilling of the body.

If the prostate is simply congested, the urine clear, the residual urine negligible and the bladder irritable with frequent and painful urination, urotropin (0.5-1.0 gm.) with acid sodium phosphate (1.0 gm.) and sedatives are useful; if urotropin is irritating it should be omitted. Bladder instillations of ten per cent. argyrol or one per cent. phenol solution are also useful. In retention without infection, the constant use of urotropin is indicated during the time of local treatment and if more than fifty c.c. of residuum is found, urotropin should be used constantly in small amounts. In the presence of infection, the treatment is that of prostatitis or retention cystitis and urotropin is given for short periods in doses as high as possible. The bowels and stomach require cathartics, enemata, gastric lavage, etc. Opiates must be given with extreme caution. For the frequency of urination, the passage of a large-sized, full curved steel sound is useful. The pelvic organs are decongested by enemata, repeated hot sitzbaths, hot rectal irrigations, prostatic massage and such drugs as urotropin with acid sodium phosphate, benzoate of soda, santal oil and the various balsams. Ergot combined with bromides is sometimes useful. Excessively acid urine is treated with a change of diet, especially a reduction of the amount of sugar and an increased intake of fluid; also the neutral or alkaline salts of sodium or potassium, or alkaline mineral waters.

In the first stage of the disease, bladder irritation must be treated with instillations of argyrol or carbolic acid, or by prostatic massage and the rectal douche. If acute retention occurs, a hot sitzbath and a hypodermic injection of morphine may be used temporarily, but catheterization becomes necessary, entailing, 1. absolute cleanliness by irrigation of the meatus before catheterization, and of the bladder afterwards and the administration of urotropin, and, 2. keeping the bladder empty. Urotropin should be administered after the catheterization and three times daily thereafter. The patient is immediately put to bed, under skilled nursing care, fluids are restricted, hot rectal irrigations are given and preparations are made for catheterization. If the patient urinates comfortably after one or two catheterizations, no further treatment is necessary. The best type of catheter to use is the relatively stiff, silk webbing catheter of the bougie or Mercier coudé type, size 18-22 F., which should be ster-

ilized by boiling and introduced carefully and gently. The urine is allowed to escape slowly and if no more than twenty ounces of urine are present, the bladder is emptied completely. With enormous distention of the bladder, only twenty ounces should be withdrawn at one time and the catheter should be left in place, properly stoppered, and the urine should be allowed to escape from the bladder at intervals of fifteen to twenty minutes until it is emptied. Then a bland solution, like boric acid or physiological saline solution, should be injected into the bladder and left there. If repeated catheterism is necessary, the same precautions must be repeated each time. As a rule, catheter treatment should be instituted as a last resort.

If retention continues, catheterization is absolutely necessary. Circumstances determine the means of keeping the patient's bladder empty. In hospital cases, a catheter is tied into the urethra, urotropin is given, the patient is kept in bed, a phenolsulphonephthalein and a blood chemistry test are made and infection is awaited. Within a few days there will be a rise of temperature, possibly chills, but if there is good drainage of the bladder and if irrigations with one in four thousand silver nitrate solution are instituted once daily, and if urotropin is continued, the reaction will subside in a few days. The phenolsulphonephthalein output will show fluctuations during the next week and finally become apparently stationary. If the polyuria has disappeared and the blood chemistry has become normal or nearly so and cystoscopy has been done, the patient is ready for operative measures, which are urged upon hospital cases. If the retained catheter does not produce the desired results, suprapubic drainage should be instituted.

In private practice, it is very much better to have a trained nurse pass the catheter as often as necessary than to maintain an indwelling catheter or suprapubic drainage. At first the catheter should be passed every time the patient has the least inclination to urinate and after a few days the frequency of urination becomes known and can be forestalled by catheterization. The patient is confined to his home and the bladder is irrigated twice daily, urotropin is given and the phenolsulphonephthalein test is made. If the bladder is emptied spontaneously, operation is not imperative but preferable, as sooner or later retention will recur. If retention continues, operation is urged as a less dangerous procedure than catheterism, provided the general condition is not such as to make the operative risk unusually great. A low phenolsulphonephthalein output is no contraindiction to operation, if other conditions are satisfactory and if the acute condition of renal reaction following the first catheterization has been passed. Chronically infected patients and those accustomed to moderate retention are good surgical risks; uninfected cases with acute retention are more likely to do badly if operated upon too hurriedly. The phenolsulphonephthalein output should be as high as possible before operation, but when this has become stationary, operation is justifiable.

Patients who refuse operation or who are unsuitable operative risks for any reason, may resort to catheterism. This should be preceded by cystoscopy to determine the conditions inside the bladder as to diverticulum and stone, and as to the size and shape of the prostate. The patient usually goes into chronic complete retention and the catheter must be passed often enough to forestall urination, usually four to six times in twenty-four hours. Asepsis and gentleness in the introduction of the catheter prolong life. The head of the penis and the hands of the patient should be kept thoroughly clean by washing. The patient is instructed to boil his catheter, anoint its end with a sterile lubricant, and, holding the catheter at a point at least two inches from its extremity, the lubricant is mopped on the end of the penis and the catheter is gently inserted into the urethra and bladder up to the point where the urine begins to flow; the bladder is emptied and the catheter is then withdrawn. The bladder is irrigated once daily with a one in four thousand solution of silver nitrate, using a douche bag raised to a level of three feet above the hips and filling the bladder with the solution two or three times up to the point of comfort. The necessity of the strictest possible asepsis must be vehemently urged upon the patient and unless the utmost gentleness is used, false passages will result to aggravate the condition.

Infection and the resulting cystitis, sooner or later are bound to follow retention. This may be combatted with medicinal treatment, such as the administration of urinary antiseptics, the formaldehyde preparations, salol, methylene blue, benzoate of soda and biborate of soda, singly or combined. If the urine is alkaline, sodium benzoate or boric acid is given three times daily, but the most effective are the formaldehyde preparations combined with acid sodium phosphate given three times daily. A good plan is to alternate one with the other at different periods. Overconcentrated and acid urines are treated with the citrate or acetate of potash, combined with alkaline mineral waters and a reduction of sugar in the diet.

Infection and cystitis combined with complete retention of urine exists either as a precedent of retention or occurs subsequently to retention as a result of instrumentation. In this condition the bladder is catheterized daily, carefully irrigated and injected with two ounces of a 0.5 per cent. silver nitrate solution, which is allowed to remain in the bladder for five to ten minutes and then withdrawn. Internal disinfectants are also indicated. Or protargol, argyrol, one to two per cent, mercurochrome, or one in three thousand acriflavin solution may be used singly or alternately at different times for irrigation of the bladder. This treatment should be continued until the cystitis is overcome so as to prevent infection of the upper urinary tract, which renders prognosis bad and operation is indicated.

With incomplete retention of urine, the amount of residual urine is insignificant in the early stages of prostatic hypertrophy, but it increases in time, necessitating either the habitual use of the catheter or prostatectomy. With infection and an active cystitis, treatment is necessary regardless of the amount of the residual urine and then the question of palliative or operative treatment must be decided. If palliative measures are decided upon, the pain and the undue frequency must be relieved, the treatment being guided by the following rules: Palliative

measures should be discontinued if, after a sufficient trial, they fail to abate the symptoms permanently. The first infection of the bladder alone is not sufficient reason for operation unless the palliative measures fail to subdue the resulting inflammatory condition. Recurrent infections of the bladder demand operative interference. The selection of the type of operation must be left to the surgeon.

Intermittent catheterism is indicated as a temporary measure to relieve temporary obstruction. Its dangers are those of septic infection, which may be reduced to a minimum with proper care, but they are always present as the necessary precautions are sooner or later disregarded. The number of patients in whom an immunity to such an infection develops are relatively rare and death is the ultimate outcome. Another danger is the immediate constitutional reaction following catheterization, which may be serious and even fatal. The third danger is an accentuation of the local irritation which it is intended to relieve. The permanent tying in place of a catheter in the bladder has been recommended, but individuals differ in their ability to tolerate the instrument in the urethra. It obviates the difficulties incident to the frequent introduction of a catheter, but it produces a moderate urethritis and epididymitis and it may cause reflex anuria. In these cases suprapubic drainage of the bladder is indicated.

Continuous catheterization, accomplished by the introduction of a soft rubber, woven, or Pezzer self-retaining catheter, may be used in certain cases of enlarged prostate with chronic retention, to keep the bladder empty and to avoid the frequent introduction of a catheter. It is indicated: 1. When the catheter is introduced with great difficulty; 2. when much bleeding follows the introduction of a catheter, usually after repeated attempts at unsuccessful catheterization; 3. when there is pain and hemorrhage from cystitis and purulent or ammoniacal urine after frequent passage of the catheter.

CONCLUSIONS

In conclusion it may be said that as a rule, the general practitioner must not hesitate to advise surgical intervention in cases of prostatic hypertrophy that he may see in the second and third stages of the disease and possibly also those in the first stage, provided the surgical risk is not too great. If radical intervention is refused or contraindicated, palliative treatment may be instituted according to the outlines mentioned. Prostatic hypertrophy is essentially a surgical problem.

As the general practitioner or family physician is usually the first to see the patient with hypertrophied prostate it devolves upon him to advise the proper course of therapeutic procedure. Owing to his intimate knowledge of the patient's physical condition, he is well fitted to judge the operability of any one particular patient, which is a most important factor in the success of surgery. Furthermore, the patient has great confidence in the family physician, who also holds an important position in the family council. He can, therefore, aid the surgeon not only by his advice, but also by the proper preparation of the patient, should surgery be indicated. By no means would I in any way want to be understood as belittling the results of surgery in hypertrophy of the prostate. On the contrary, it is the only method of obtaining ultimate relief in properly selected cases and at the proper time, and the physician who fails to recommend surgery in such cases may be guilty of malpractice. None of the tests for the determination of the operability of a case or the treatment that I have mentioned should be beyond the knowledge or ability of the family physician. He owes it to himself and to the patient to be proficient in all of them and by their proper application he can do much to relieve the patient and direct him toward recovery.

Four Cases of Epithelioma of the Penis Treated by Radium*

ARCHIE L. DEAN, JR., M.D.,
New York

I present herewith for your consideration four cases of epithelioma of the penis. These patients were treated at the Memorial Hospital in the department of urology. I chose these particular cases because each represents a different method of attacking the problem of penis cancer.

Case I.—Extensive lesion, radical operation, recurrence, x ray treatment. The patient, W. W., in October, 1919, noticed a small sore at the meatus, which gradually increased in size until it obstructed the flow of urine. Finally the entire glans was involved. Amputation with groin dissection was performed in Bellevue Hospital on October 1, 1919. In December, 1919, the patient was referred to the Memorial Hospital with enlarged hard lymph nodes in each groin, and thickening beneath the operative scars.

Treatment: Five x ray exposures in 1920 at intervals of one month. In January, 1921, three similar treatments at one week intervals, as follows: six minutes, four milliamperes, four mm. aluminum filter, ten inch spark gap, ten inch focal distance.

Case II.—X ray to local lesion, local amputation. The patient, J. H., in November, 1920, noticed a small growth on the left side of the glans penis, which gradually increased in size while being treated with caustics. Examination at the Memorial Hospital on February 25, 1921, showed that on the dorsum of the penis, involving the under surface of the prepuce, was a papillary growth two cm. in diameter. It was sessile, and the base indurated. There was no inguinal adenopathy. On August 30, 1921, the

*Presented before the Section in Genitourinary Surgery, New York Academy of Medicine.

local growth had progressed in spite of x ray therapy, in addition seemingly malignant nodes had developed in either groin. On September 15, 1921, amputation was performed with dissection of groins, leaving 324 mc. hrs. of silver filtered radium in the left groin.

Case III.—Radium alone to local lesion. Patient T. H. stated that about thirty years ago a small sore appeared on the penis which persisted for three years, finally clearing up under local treatment. In October, 1920, a slight recurrence was noted which had been growing larger. A sharp burning pain was felt. Patient visited the Presbyterian Hospital where a biopsy was performed, and when the diagnosis was returned carcinoma, he was referred to the Memorial Hospital. On October 28, 1921, there was noted on the dorsum and left side of the penis a raised, pink lesion scabbed over in spots. It measured two by three cm. in size. There was no definite inguinal adenopathy. On November 1, 1921, a dental compound applicator was employed, giving a dose of sixty mc. hrs. to the sq. cm. with a filter of one half mm. of silver. On February 14, 1922, a small area, previously untreated, received a similar application. In addition the groins received one prophylactic x ray exposure.

Case IV.—Patient J. W. noticed a small sore on the penis in February, 1923. It had been increasing in size, but caused no pain or discomfort. He was referred from Bellevue Hospital to the Memorial Hospital after a diagnosis had been made. On August 8, 1923, the frenum seemed replaced by a papillary tumor measuring two by one cm. in size. Induration was marked. No inguinal adenopathy. Six bare tubes of radium emanation each of 0.21 mc. were imbedded into the tumor as superficially as possible.

This patient was shown not at all as a final result, but because he had been examined a few weeks previously when Dr. Parounegian presented him before the section in dermatology, when the radium reaction was at its height and his circumcision had not healed.

The Pseudouremias Compared with True Uremia*

Report of Four Cases with Necropsy

By HENRY M. FEINBLATT, M.D.,
Brooklyn, N. Y.

In two previous articles on the subject of uremia (1), a separate study of the syndrome of nitrogen retention was reported. By tabulating and analyzing the manifestations exhibited by patients with known nitrogen retention, a symptom complex was worked out which bears a close resemblance to the syndrome shown by nephrectomized animals and cases of total ablation of renal function in man. The most important element in this symptom complex is the absence of certain phenomena which play a conspicuous part in the common descriptions of uremia. Convulsions were never observed except just before death. Delirium was infrequent. Transient paralyses did not occur. Visual disturbances, except those due to changes in the fundus oculi, were rare. The essential symptoms associated with the syndrome of nitrogen retention proved to be drowsiness, gradually merging into coma, vomiting, restlessness, headache, increased tendon reflexes, and muscular twitchings.

In this paper I shall endeavor to contrast the syndrome of nitrogen retention (true uremia) with the various other terminal states occurring in nephritis (the pseudouremias). It is not intended to give the impression that the pseudouremias are in themselves definite clinical entities; in fact, the pseudouremias, as here considered, constitute a heterogeneous group. They occur in nephritis but are not due to renal inadequacy *per se*. They are conditioned by extrarenal lesions, which may in turn be a result of the existing nephropathy.

Four case histories are here reviewed, with the necropsy findings in each. An instance of bichloride poisoning with total anuria was selected as an example of true uremia (loss of renal function). Contrasted with this case three examples of the pseudouremias are described. Because of the coexistence of nephritis and the symptoms commonly described as characteristic of uremia, the clinical diagnosis of uremia had been made in each of these individuals, in spite of the absence of nitrogen retention. However, in each instance, the necropsy revealed sufficient cerebral disease to account for the clinical evidences observed without invoking the diagnosis of uremia. This diagnosis had simply served to cloud the issue in these cases and to divert attention from the cerebrum.

Without attempting to be too inclusive, the following schedule is suggested as a working basis for a classification of the general group commonly bunched together under the heading of uremia.

CLASSIFICATION.

I. Uremia: the syndrome of nitrogen retention.
II. Pseudouremias: absence of nitrogen retention.
1. Cerebral group:

a. Focal edemas: characterized by convulsions, amaurosis, evanescent hemiplegias, astereognosis, paresthesias, etc., due to edema of cortical centres.

b. Vascular accidents: when associated with advanced nephritis, these are often overlooked, because a vague hemiplegia with coma can so readily be called uremia.

c. Cerebral arteriosclerosis: disturbed cerebral function according to location.

*From the Department of Internal Medicine, Long Island College Hospital and the Medical Service of Kings County Hospital.

2. Cardiovascular group:
   a. Manifestations due to hypertension.
   b. Manifestations due to myocardial insufficiency.
   c. Manifestations due to cerebral arteriosclerosis (*l. c*).
3. Pulmonary group.
4. Miscellaneous group, including syndromes due to gastrointestinal conditions, complicating infections, etc.

The diverse nature of the conditions enumerated in the classification given above shows how all inclusive the term uremia, as commonly used, may be. It forms a strong argument in favor of limiting the term uremia to the syndrome of nitrogen retention.

TRUE UREMIA.

CASE I.—True uremia; total loss of renal function due to anuria consequent upon bichloride poisoning.

The patient, A. C., female, married, twenty-five years old, born in the United States, entered the Long Island College Hospital on April 29, 1919, with a history of having swallowed three bichloride tablets on the previous evening. A physician had promptly administered an antidote, washed out the stomach, and sent her to the hospital. The patient's mother had died of Bright's disease, otherwise the family history was negative. She had had pneumonia, scarlet fever and measles as a child, and typhoid at the age of eight.

On admission the patient complained of nausea and headache. The temperature was 99.4° F.; pulse, 85; respiration, 22. Physical examination was negative. The systolic blood pressure was 105 mm., diastolic 75 mm. Except on May 5th, when a few c. c. of urine were obtained by catheter, the patient was totally anuric. This specimen was of a dirty brown color and contained an abundance of albumin.

The blood chemical findings are tabulated below:

Date	Urea Nitrogen	Uric Acid	Creatinin	Sugar
May 3, 1919	117.6	....	8.	142.9
May 4, 1919	86.8	....	10.2	....
May 5, 1919	140.	....	13.3	166.6
May 7, 1919	121.8	14.1	14.8	250.

Up to May 4th the only symptoms observed were headache, nausea, occasional vomiting and anuria. At this time the patient became drowsy and listless. The drowsiness gradually increased, merging into a semicomatose state on May 8th, the date of death. No convulsions, visual disturbances, delirium, paralyses, dyspnea, or edema were observed at any time during her illness. Necropsy revealed the following findings: The kidneys were swollen and soft, and showed marked areas of cloudy swelling with portions of true necrosis. Microscopically, the epithelium of the tubules was badly damaged. The tubules were distended and contained desquamated epithelium and casts. The glomeruli were normal, and the capsules of Bowman showed no changes.

This combination of extensive coagulation necrosis of the tubules with intact glomeruli is characteristic of the bichloride kidney, constituting a pure type of the nephrosis of Volhard and Fahr. The conditions in this case were similar to those of a scientific experiment. An individual, previously in good health, was suddenly deprived of all renal function, and she remained in that condition up to the time of her death. Her symptoms were few in number and unspectacular in nature. Headache, vomiting, drowsiness terminating in coma, anuria, rising blood pressure, and nitrogen retention were the only manifestations. No convulsions, visual disturbances, delirium, paralyses, dyspnea or edema were observed at any time.

PSEUDOUREMIA.

CASE II.—Pseudouremia, cerebral group, focal edema type; acute nephritis with convulsive and amaurotic phenomena.

The patient, A. K., male, single, forty-two years old, Lithuanian, entered the Kings County Hospital on January 21, 1922, in coma. The only history that could be obtained was that the patient had become violently intoxicated on New Year's Day and that he had been drinking heavily ever since. About January 12th he complained of loss of vision, and a few days later he began to have convulsions. At about the same time he complained of headache and had a spell of vomiting. On admission he was unconscious and was having severe convulsions. There were tetanic spasms of the entire musculature recurring at intervals of thirty minutes, alternating at times with clonic seizures. The convulsions were so severe as to shake the entire bed. The tongue was badly bitten, the mouth was full of blood and the lips were frothy, and several teeth had been loosened by the violence of the paroxysms. There were involuntary evacuations of urine and feces. The temperature was 101° F., pulse 144, respiration 52. The systolic blood pressure was 215 mm., diastolic 130.

The patient was a well developed, well nourished man. The eyes were closed and deviated to the right. The pupils were equal, regular, and of average size, but reacted feebly to light. The heart and lungs were negative. The ophthalmoscopic examination showed a slight fulness of the veins, indistinctness of the disc margins, and a small retinal hemorrhage in the right fundus. The urine had a specific gravity of 1,020, with a heavy trace of albumin, many red and white blood cells, and a few hyaline casts. The blood chemical examination (January 21st) gave the following readings: Urea N. 16.3 mg., creatinin 1.5 mg., and sugar 120 mg. to 100 c. c. of blood. A spinal tap performed soon after admission showed the fluid to be under increased pressure. Following the puncture, the convulsions ceased, the patient became quiet, and the pulse and respiration became slower and stronger. By January 23rd the patient had regained consciousness, but was still very weak. Soon afterward the pulse became progressively weaker and the breathing more labored. Death occurred on January 30th. The final clinical diagnosis was acute diffuse nephritis with uremia; bronchopneumonia.

Necropsy revealed the following findings: The brain was edematous. There was marked cloudiness of the piaarachnoid over the left temporal lobe and in the occipital region, particularly at the occipital pole, where marked congestion was present. The right kidney weighed 320 gm., the left 375 gm. The capsules stripped with great difficulty. Fetal lobulations were present. On section the cortical width was increased. The parenchyma had a mottled appearance. The glomeruli stood out rather prominently as injected points. The microscopic picture

was that of acute diffuse nephritis. The heart weighed 490 gm. The free edges of the mitral valve contained distinct nodular thickening. The upper lobe of the right lung was the seat of a confluent bronchopneumonia; the other lobes were congested and edematous.

It is upon such cases as this that Traube's theory, which ascribed uremia to edema of the brain, was built. Convulsions and amaurosis, particularly where the spinal fluid is under increased pressure and rachicentesis gives relief to these symptoms, are usually attributable to cerebral edema. This lesion is not believed to be a postmortem or an agonal change. Transient paralysis or anesthesia, aphasia, astereognosis, and cortical deafness should undoubtedly be included in the same category, the functional defect depending upon the cortical area involved in the focal edema.

SUMMARY.

This paper aims to contrast the syndrome of nitrogen retention (true uremia) with the various other terminal states occurring in nephritis (the pseudouremias). Four clinical cases, one of true uremia and three instances of the pseudouremias, are described with the necropsy findings in each.

A case of bichloride poisoning with total anuria was selected as an example of true uremia. The only manifestations observed in this patient were headache, vomiting, drowsiness terminating in coma, anuria, rising blood pressure, and nitrogen retention. Convulsions, visual disturbances, delirium, paralyses, dyspnea, and edema, symptoms which play so prominent a part in the common descriptions of uremia, were at no time observed. The kidneys at necropsy revealed a pure type of the nephrosis of Volhard and Fahr.

Three other case histories are reviewed, in each of which the patient was suffering from nephritis without nitrogen retention. All of these patients were in coma, and two exhibited convulsions and amaurosis. In one instance the convulsions ceased and the patient emerged from coma following rachicentesis. In all three cases the final clinical diagnosis of uremia had been made in spite of the absence of nitrogen retention. At necropsy cerebral edema was found in the two patients in whom convulsions and amaurosis had been observed. The clinical and postmortem findings in these two cases tallied with Traube's old description. The third patient disclosed a cerebral hemorrhage at necropsy.

The common description of uremia includes too many diverse conditions. It is felt that the term uremia should be limited to the syndrome of nitrogen retention. Certainly, the three clinical cases described as instances of the pseudouremias differ radically from the syndrome exhibited by the patient with bichloride poisoning.

An attempt to classify the pseudouremic states shows how heterogeneous this group really is. If the term uremia is used in such a general sense as to include all of these conditions, it must necessarily be correspondingly lacking in definite significance. This fact forms a strong argument in favor of limiting the term uremia to the syndrome of nitrogen retention.

This study included two additional cases of pseudouremia of the cerebellar type which were omitted on account of lack of space. They will appear in the author's reprints.

Malignant Growths of Prostate and Bladder*

B. S. BARRINGER, M.D.,
New York

CARCINOMA OF PROSTATE

Case I.—The patient, Mr. L., first came to the Memorial Hospital in June, 1921, at the age of seventy-two, with a tumor of the bladder. Because of his age, it was thought inadvisable to operate, and he was treated with radium through the cystoscope. That was not successful, so he was operated upon and the entire right half of the bladder was found to be a papillomatous mass. At the base of this mass was a good deal of induration, and because of the extent of the growth it was thought that not much could be done for it. However, the papillomatous mass was taken off and in the indurated base 20 bare tubes=7.84 m. c.=1038 m. c. hours were implanted. On top of this screened radium 3 tubes=110 for 6 hours=660 m. c. hours was placed, to get the portions that might have been missed by the bare tubes. The patient's convalescence was rather stormy, but he left the hospital a month and a half after the operation. He has a fairly tortuous urethra which is very sensitive, but he does not get up at night to urinate. He was perfectly well about two and a half years after operation. The growth taken from the surface showed a papillary carcinoma of the bladder.

CARCINOMA OF NECK OF BLADDER

Case II.—The patient, Mrs. H., showed another way of treating carcinoma, that is, without operation. She came to the Memorial Hospital in March, 1922, with a red papillary growth growing from "one to five o'clock" on the bladder neck, very near the left ureter. On the surface was some slough. There was no induration per vaginum. On three different occasions, because of the inaccessibility of the growth, bare tubes alone were planted in the base of the growth. Dr. Ewing reported the specimen to be a papillary carcinoma. When cystoscoped about a

*Case reports presented at a meeting of the Genitourinary Section of the New York Academy of Medicine.

month ago, her bladder was clean and she had no symptoms. She has now gone free for twenty months. The x ray pictures presented show the progress of the destruction of the tumor. In the fourth month of 1922 she had four bare tubes of five m. c. buried in the tumor, and before that she had five bare tubes of five m. c. each in the tumor. In all she received three treatments to destroy the tumor. On account of the inaccessibility of the growth it would have been difficult to operate on the tumor alone.

SQUAMOUS CARCINOMA OF BLADDER WALL

CASE III.—This case is interesting in that it shows a different type of tumor. The patient, Mr. M., came to the Memorial Hospital in December, 1920, being then fifty years of age. He had suffered from burning and frequency for three months and later had hematuria. He was operated upon because the cystoscope showed a number of good sized tumors on the anterior bladder wall one being four by three cm. in extent, flat and infiltrated. Because of the bad type of the tumors he was given a very heavy dose of radium, twenty-one bare tubes, totalling about ten m. c., being implanted in the base of the tumors. In addition he had packed against the tumors three tubes of screened radium equalling 43 m. c. for ten hours, so that he had 430 m. c. on the surface.

The patient had a stormy convalescence and a good deal of trouble afterwards. Stones were formed on top of the slough, one a good sized stone which could not be crushed. He was operated upon again and a large stone was removed from his prostatic urethra. At that time no tumors were seen in the bladder. After this he healed up without further difficulty and now, two years and eleven months later, he is in good condition. According to Dr. Ewing's report the growth was squamous carcinoma, infiltrated. In an article from the Mayo Clinic it was stated that out of 133 bladder tumors six squamous tumors were found, three of which were operable. In the three operable cases, one patient was alive, five or six years after the operation was performed. Squamous carcinoma is one of the bad types of tumor.

SARCOMA OF BLADDER

CASE IV.—This is a case of sarcoma of the bladder, which is rather rare. The patient, a man, was fifty-four years of age when he came to the clinic on June 9, 1920. At that time he had had an enucleation of a gland at the right side of the trigon. This was done by Dr. Lewisohn of Mount Sinai Hospital, who did not know just what it was; he thought it was an aberrant gland of Albarran and kindly referred the man to the Memorial Hospital. The wound was opened and examination revealed a tumor on the right side of the trigon about two and a half centimetres square, sloughing and with some induration at the base. It seemed to be malignant, so a specimen was taken and radium was implanted. Dr. Ewing reported it to be a myosarcoma of low malignancy—not of the high malignancy rapid growth type usually found. After the operation, the patient's prostate began to enlarge, and on five different occasions he had radium needles inserted into the prostate through the perineum, in an effort to control the growth. On January 7, 1922, cystoscopy showed scar tissue and no tumor. His prostate is now flat and scarred, three and a half years since he was first operated upon. A sound has been passed occasionally, but the patient has had no radium treatment since 1921.

In these days when deep x ray therapy is being advocated in place of radium for the treatment of prostatic carcinoma, it is interesting to see that occasionally radium does accomplish something in such cases. Personally, I have seen x rays do little for prostatic carcinoma and I feel that radium does considerably more, though neither gives brilliant results.

CARCINOMA OF PROSTATE

CASE V.—In 1915, Dr. Downes performed a prostatectomy on Mr. P. at St. Luke's. The pathological examination of the prostate showed it to be carcinomatous. Soon after the operation the patient's prostatic urethra began to close down and he had trouble in urinating. He did not come to the Memorial Hospital until a year and two months after the prostatectomy.

The patient had in that time been treated with fulguration, without success. At first no instrument could be passed into the urethra; the prostate was small and rather soft and the true character of the carcinoma was not discovered until after the radium treatment, when the tissues were shrunken and one could feel the indurated carcinoma. The case was treated by simply keeping at it, a little at a time, not enough to upset the patient, and having intervals of two or three months between treatments. That seemed to be the best method of treating prostatic carcinoma. The method followed seemed to give the patient little discomfort. He has had no treatment for several years, and it is now six years since his appearance at the Memorial Hospital. He is working daily, and his health seems to be perfectly good. He has not had any radium treatment for two or three years. His prostate is a little scarred and irregular.

CARCINOMA OF BLADDER BASE

CASE VI.—The patient, Mr. H., aged forty-eight, was first seen on December 10, 1918. He had had a previous cystotomy and cauterization of the tumor at the base of the bladder, about six months earlier. At first an effort was made to treat him without operating. The pathological report of the Brooklyn Hospital where he had been treated was either papilloma or papillary carcinoma. Finally he was operated upon in September, 1919. A cystotomy was done, which revealed many irregular tumors of the bladder base, hard and indurated. None of them was large, but altogether there was an extensive infiltration of the bladder base. Bare tubes were then put into these tumors and filtered radium packed on the outside of the tumors. That was four years and eleven months ago. He recovered without much trouble, but has not been cystoscoped since. He is feeling well, and is working all the time. The case should be classed as an infiltrating carcinoma of the bladder base, which was well for nearly five years.

134 EAST SEVENTY-SIXTH STREET.

Pyelitis in Children

I. RUSSEL KUHN, M.D.,
South Fallsburg, N. Y.

Of the febrile diseases in children, possibly none is more often overlooked than pyelitis. Fever, in a general way, indicates the presence of an infection. Most of the fevers of short duration have an unknown etiology and origin and many of the terms applied to them, as grippe, rheumatoid fever, cold, intestinal disorders or teething are called cryptogenic fevers. Many of these socalled nonspecific fevers really are due to pyelitis. Its recognition is usually a simple matter, and yet the possibility of its occurrence is forgotten and the urine of an infant so infrequently examined. Unrecognized acute pyelitis in infancy may give rise to fever varying from a slight to a most extreme degree with severe constitutional disturbances.

It is well known that lower forms of animal life are usually eliminated by the kidney without damage to the pelvis. When because of diminished local resistance or increased bacterial virulence, the pelvis of the kidney becomes damaged, pyelitis follows. Of the various bacilli, it is the colon bacillus that is most frequently found. The bacterial invasion of the kidney may occur in various ways: the hematogenous method of invasion is by far the most common and next the urogenous. Otitis media and tonsillitis have often been followed by acute pyelitis. It occurs at times as a complication of influenza, typhoid fever, diphtheria and scarlet fever. At times, an ascending infection from the bladder occurring almost invariably in female infants is the cause. There is an interesting relationship between diarrhea and acute pyelitis which leads one to suspect that the intestine may be the source of infection.

The clinical picture often presents itself with a striking and abrupt onset. The child has a sudden chill and the temperature varies from a 101° to 105°. At times nervous symptoms are so marked that one is led to think of an acute cerebral disease. The child may be excessively drowsy with neck stiff and even head somewhat retracted. There may, on the other hand, be convulsions. Vomiting and diarrhea are frequently early symptoms. Less frequently, especially in older children, there is some tenderness over the abdomen, at times even simulating appendicitis. The physical examination of an infant suffering with pyelitis is often entirely negative except for a puzzling and prolonged temperature usually for several weeks which shows little signs of abating. There is nothing to call attention to any abnormality of the urine until it is examined microscopically. Urine which to the naked eye is apparently clear and which shows very little albumin will at times give severe symptoms. One should not be misled by the gross appearance of the urine, but a microscopical examination should be made routinely in every child, particularly where physical examination shows nothing to account for the presence of high fever. The urine is usually acid and under the microscope shows a number of pus cells grouped together. Baccilli can also be seen in the field.

Pyelitis secondary to otitis media and tonsillitis is well shown in the following cases:

Case I.—H. S., female, aged five, complained of earache. Physical examination on June 26th showed temperature of 104°, throat congested, right drum inflamed. Right membrane cleared up in a few days, but the child became drowsy and temperature did not drop. Examination of urine showed a moderate number of white blood cells and a faint trace of albumen. Macroscopically, the urine appeared apparently clear. Under appropriate treatment, the child made a complete recovery.

Some cases, however, do not respond to treatment, and in spite of everything exacerbations occur.

Case II.—H. S., female, aged five, first seen in September, 1922, became ill with chills, cough and temperature. Examination showed tonsils enlarged, rest of examination negative. She gave a history of having had pyelitis following measles two years ago. Examination of her urine showed a few white blood cells. Child felt well one week later, but urine still showed a few pus cells. A few months later, January, 1923, child complained of nausea and vomiting, temperature 102°. Uranalysis again showed many white blood cells. Child was ill for five weeks when urine again became clear. Since then the child has had repeated attacks, and in spite of medical treatment, including vaccines, her urine at times will show white blood cells which will give her systemic disturbances.

The prognosis of pyelitis is generally good. The treatment of pyelitis is to remove the pus by giving large quantities of water to flush the kidneys unless they themselves are involved as in nephritis. The importance of the alkalinization of the urine cannot be overestimated. The drug most generally used is potassium citrate and must be given in doses large enough to make the urine alkaline. Care, however, must be taken not to disturb digestion or set up diarrhea—a condition which happens when the potassium salt is given in too large or frequent doses. A good substitute, then, is sodium bicarbonate. At times, the alkalies fail, and it is then that hexamethyleneamine should be tried. Salol and methylene blue are also given at times. The reaction of the urine is a very important factor in the medical treatment. When, as occasion happens, the reaction of the urine is alkaline, ammonium benzoate or acid sodium phosphate should be given. Vaccine treatment of pyelitis is still on controversial grounds. It should be tried, however, in obstinate cases where remissions and exacerbations occur.

In conclusion, it may be said that pyelitis is a disease occurring almost exclusively in females and, though simple in diagnosis, is often overlooked. The most frequent form of invasion is the hematogenous and the source of infection is usually remote from the pelvis of the kidney as tonsil, ear, intestine. Recognized early, it responds, as a rule, very satisfactorily to medical treatment.

Every-Day Prophylaxis

NEVER was there a time when the necessity for protecting the nose, mouth and throat against infection was so generally recognized as it is today.

For this reason, never was the need so great for an antiseptic that medical men can recommend with absolute confidence not alone in its germ-destroying powers, but also in its freedom from toxic, irritating or other objectionable action.

Fortunately in

Dioxogen

the practicing physician has at his command an antiseptic that he can use or recommend for every day use with complete confidence, that it will give the protection he wants, without the slightest disagreeable or harmful effect.

Owing its action entirely to the liberation of pure oxygen—Nature's own antiseptic—Dioxogen when used according to the directions herewith, has been found an ideal gargle, mouth wash and nasal spray.

Dioxogen, therefore, has the great advantage that it can be recommended for the foregoing purposes in the home, with the gratifying knowledge that it can be employed as freely as necessary or desirable.

DIRECTIONS

"Three teaspoonfuls of Dioxogen—the oxygen antiseptic — in a scant half glass of warm water makes a non-toxic, non-irritating and effective gargle, mouth wash and nasal spray that the practitioner can use and recommend as freely as he desires with every confidence that it has no superior as a means of protection against germ infection."

An ally of preventive medicine—
KELLOGG'S BRAN

RIGHT in line with the objective of modern medicine is Kellogg's Bran, cooked and krumbled.

It is an ally in preaching the ounce of prevention rather than the pound of cure.

Its purpose primarily, of course, is the relief of constipation. And because it is **ALL BRAN**—not mixed with other elements—it accomplishes the results you expect of it.

Kellogg's Bran is equally valuable in preventing constipation—in keeping the intestinal tract open, and functioning naturally.

It will be eaten regularly, too, on your prescription. Kellogg's Bran has a most appetizing flavor—totally unlike ordinary, unpalatable bran.

We consider it a pleasure to send any physician a full-size package of Kellogg's Bran, without obligation. A request on a postal is sufficient.

Kellogg's

Strychnine Medication

Strychnine is the therapeutic sheet-anchor for stimulating nerve protoplasm incapable of performing its normal functions, but in some conditions there is marked intolerance to strychnine even in small doses. When, however, it is exhibited as strychnine glycerophosphate and combined with sufficient calcium and sodium glycerophosphates, as in

ESKAY'S
NEURO PHOSPHATES

there is increased toleration. The destructive action of the alkaloid strychnine is apparently repaired by the constructive action of the glycerophosphoric acid. Many who cannot take the usual strychnine salts can take Eskay's Neuro Phosphates.

A Sedative or a Tonic?

Most cases of neurasthenia and "nervous break-down" result from physical debility. They require, not a sedative, but a tonic.

Compound Syrup of Hypophosphites "FELLOWS"

has proved its efficacy in thousands of cases of this kind. It is a real tonic, not merely a "whip." It promotes nutrition and vital energy, and thus controls nervous irritability.

How Pepsodent Differs

Its modern principles and unique effects

Reasons for its world-wide vogue

Pepsodent is based on new dentifrice theories. On the dominant theories of today, expounded by many modern dental investigators.

Those theories are gaining ground and Pepsodent gains with them. Now many thousands of dentists the world over endorse and advise this method. And millions of people of some 50 nations have adopted Pepsodent, largely through that advice.

The acid principle

Former tooth pastes based on soap and chalk had alkaline reaction. Pepsodent omits all soap and chalk, and is mildly acid.

Mild acid acts to disintegrate the mucin plaque—to curdle or flake it—at all stages of formation. Food acids would do likewise. But Pepsodent, when rightly used, applies the acid wherever plaque may lodge.

Mild acid increases the salivary flow and reduces its viscosity. It increases the alkalinity of the saliva. It increases the ptyalin in the saliva, the digestant of starch deposits.

Those are natural effects and essential. Nature's tooth-protecting forces need that stimulation. Right diet affords it. But Pepsodent brings it regularly, regardless of the diet. Any alkaline dentifrice, of course, brings just opposite effects.

Proper cleansing

Proper cleansing requires a right polishing agent. Not only to remove food debris and deposits, but disintegrated plaque.

Chalk is incompatible in an acid tooth paste. Pepsodent employs a blend of finely powdered calcium phosphate and anhydrous calcium sulphate. This blend is far softer than enamel. In the pure form, as we use it, it is considered the ideal polishing agent.

Some misconceptions

Absence of soap makes the polishing agent conspicuous. This leads to misconceptions.

But the polishing agent is not severe, not harmful to enamel. Natural teeth have been brushed with Pepsodent up to 250,000 times without any ill effects.

Natural instinct questions the effect of acid on the teeth. But mild acid is natural and essential, a part of proper diet. The use of Pepsodent merely insures regularity in its effects.

Natural teeth have been immersed for four years in Pepsodent mixed with saliva, as overwhelming proof that the acid cannot harm.

Please ask questions

Pepsodent is right in principles and effects. If you ever doubt that, please ask questions. Competent men will reply. Authoritative literature will be sent, based on seven years of tests.

Send the coupon for latest information, also a tube to try.

ILETIN (INSULIN, LILLY)

In the Treatment of Diabetes

Purity, Stability and Constant Unitage Essential to Satisfactory Results

As a result of almost two years of research and experience in the production of Iletin (Insulin, Lilly), we are able to guarantee the purity, stability and constant unitage of the product.

STABILITY AND PURITY—The initial difficulties associated with its production, which were very great, have been almost entirely overcome. Manufacturing operations are conducted on a large scale by processes which have been found through wide experience to give a uniformly pure product which exerts the desired physiological effect. Iletin (Insulin, Lilly) is free from toxic substances and test lots show no deterioration over a period of more than a year.

UNIFORMITY—From a therapeutic standpoint it is of great importance that different lots of Insulin be constant in unitage. The maintenance of this constancy in successive lots is one of the most difficult problems of the manufacturer. Through the opportunities for studying this question afforded in the making of many large lots of Iletin (Insulin, Lilly) it has been possible to develop an elaborate system of standardization which enables us to guarantee the unitage within quite narrow limits. This affords the patient the protection against disturbances which may follow a change from one lot to another if the lots in question are not uniform.

On account of its uniformity in purity and unitage, Iletin (Insulin, Lilly) has given good results in the past and may be relied upon to give uniformly satisfactory results in the future.

Supplied through the drug trade in 5 c. c. ampoule vials, U-10, U-20 and U-40, containing 50, 100 and 200 units respectively. Send for pamphlet.

ELI LILLY AND COMPANY

INDIANAPOLIS, INDIANA, U·S·A

In cases of Dermatitis Calorica apply Antiphlogistine *cold*

IN cases of Dermatitis Ambustionis Erythematosa, where there is redness, accompanied with more or less heat of the affected part and slight swelling, apply Antiphlogistine as a *cold* dressing.

The hygroscopic properties of Antiphlogistine

are particularly valuable in cases of Dermatitis Ambustionis Bullosa. Aside from excluding the air, and relieving the smarting, the vesicular eruption and bullae are reduced, the serous exudate is deposited in the dressing, and the reparative process is greatly aided.

Antiphlogistine is an important "first aid" in all forms of inflammation, superficial or deep-seated. It absorbs the water from swollen tissues, relieves the pain, and acts in a physiological manner to re-establish normal circulation in the inflamed part.

When Antiphlogistine is used in time, suppuration following destruction of tissue, is often prevented.

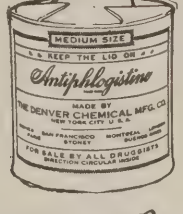
Over 100,000 Physicians use Antiphlogistine regularly; it may be obtained at any Pharmacy.

Let us send you our free sample package and literature about Antiphlogistine, the world's most widely used ethical proprietary preparation.

The Denver Chemical Mfg. Company
New York, U. S. A.
Laboratories: London, Sydney, Berlin, Paris, Buenos Aires, Barcelona, Montreal, Mexico City

Antiphlogistine
TRADE MARK

"Promotes Osmosis"



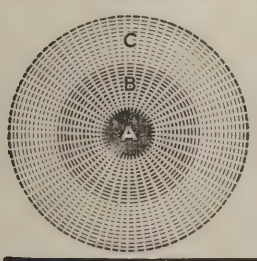


Diagram represents inflamed area. In zone "C" blood is flowing freely through underlying vessels. This forms a current away from the Antiphlogistine, whose liquid contents, therefore, follow the line of least resistance and enter the circulation through the physical process of endosmosis. In zone "A" there is stasis, no current tending to overcome Antiphlogistine's hygroscopic property. The line of least resistance for the liquid exudate is therefore, in the direction of the Antiphlogistine. In obedience to the same law exosmosis is going on in this zone, and the excess of moisture is thus accounted for.

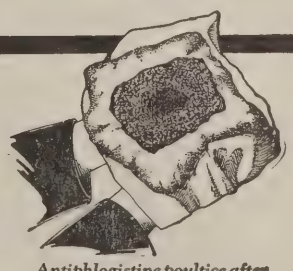

Antiphlogistine poultice after application. Center moist. Periphery virtually dry.

Here is the *ideal* treatment for Hay Fever

15-dose Series Mulford Pollen Extracts in Ever-Ready Hypo-Units

The thousands of physicians who use MULFORD HAY FEVER TREATMENT base their preference on the following points of excellence:

Advantages of Product

Prepared from pollens carefully selected, sifted and dried.

Stable in solution, thus avoiding inconvenience of mixing before use.

Accurately standardized, in terms of protein units.

Highest therapeutic and diagnostic value.

Advantages of Package

The MULFORD HYPO-UNIT package is the last word in convenience, safety and accuracy.

Each HYPO-UNIT contains one accurately measured dose, and is sterile and completely assembled, ready for instant use.

Used once, then thrown away, a feature appreciated by patient and physician alike.

Three intradermic tests supplied with each 15-dose treatment, to permit testing patient's increased tolerance during course of treatment.

Dosage

Desensitizing treatment, recommended for best results, should begin 4 to 8 weeks before attack is due, and 15 doses or more, of increasing strength, should be given. When the specific pollen appears in the air, doses should be greatly reduced.

How Supplied

TIMOTHY POLLEN EXTRACT, RAGWEED POLLEN EXTRACT and WORMWOOD POLLEN EXTRACT are furnished as follows:

15-Dose Treatment, including 3 Intradermal Tests and 15 Hypo-Units (doses 1 to 15)
4-Syringe Package (A, B, C and D strengths)
1-Syringe Package (D, E or F strength)
5 cc Vial (D or E strength)
20 cc Vial (D strength)

Free cutaneous tests and literature sent to physicians on request

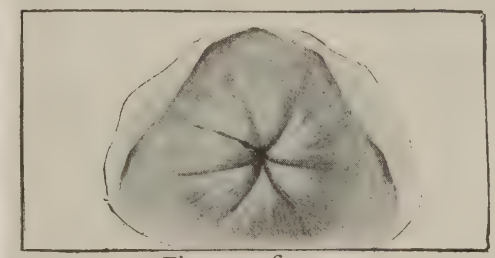
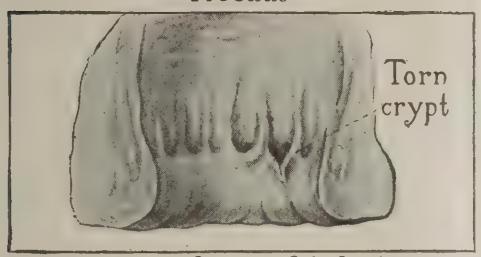
THE PIONEER BIOLOGICAL LABORATORIES

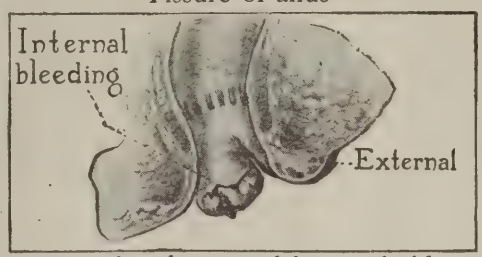
Proctitis



Fissure of anus



Cryptitis (focus of infection)



Internal and external hemorrhoids.

LUBRICATION THERAPEUSIS
IN RECTAL AND ANAL PATHOLOGY

PROCTITIS: According to a noted proctologist, inflammation of the rectal mucosa is much more common than is generally thought. The indications for treatment are to produce a soft evacuation and to lubricate and soothe the bowel wall. Nujol accomplishes this and also reduces the time during which the fecal mass is held in contact with the inflamed mucosa, thus quickening the healing of the membrane.

FISSURE: The dry, hard feces when forced over the delicate mucous membrane of the anal canal cause it to erode, leaving an open wound. Nujol softens the feces and lubricates the intestine. Thus it prevents fissure formation or encourages healing by preventing irritation and infection.

HEMORRHOIDS: Rectal inflammation and fecal impactions prevent the proper flow of venous blood into the portal circulation. This is accentuated by the absence of valves in the rectal veins and man's upright position, but particularly by straining at stool. Nujol, by its softening, lubricating action, enables the feces to be evacuated without straining. Thus, by removing one of the conditions which causes and aggravates hemorrhoids, Nujol brings comfort and relief to the patient, often leading to ultimate disappearance of the trouble.

CRYPTITIS: A frequently overlooked cause of painful defecation and a source of systemic infection. The hard fecal lumps are kept soft by the regular administration of Nujol. Nujol also forms a lubricating coat over the crypt, thus favoring healing and relieving the pain.

Nujol, the ideal lubricant, is the *therapeutic common denominator* of all types of constipation. Microscopic examinations show that too high a viscosity fails to permeate hardened scybala. Too low a viscosity tends to produce seepage. Exhaustive clinical tests show the viscosity of Nujol to be physiologically correct and in accord with the opinion of leading medical authorities.

Nujol

International Medical Annual 1924

International Medical Annual. A Year Book of Treatment and Practitioner's Index. By 31 Eminent Specialists. Edited by CAREY F. COOMBS, M.D., F.R.C.P. (Medicine) and A. RENDLE SHORT, M.D., B.S., B.Sc., F.R.C.S. (Surgery). Over 500 pages, 146 text illustrations and 54 plates, 14 in colors. $5.00 net. Published for the regular subscribers. Not many extra copies available.

THE 42nd edition of this famous annual review brings your entire library up-to-date and is indispensable to any practitioner who conscientiously endeavors to keep abreast with the rapid progress in all departments of medicine and surgery. As a means of quick reference to the newer methods in every field it is unique and invaluable. Its preparation has involved an immense amount of work on the part of thirty-one eminent American, British, and French specialists. There are more than 200 references to American literature which can be easily followed up if desired so that it is truly a review of American medicine and surgery as well as the world-wide field. The subjects covered include:

General Medicine—General Surgery—Diseases of the Eye, Ear, Nose and Throat—Diseases of the Heart, Blood Vessels, and Respiratory Tract—Gastro-Intestinal Disorders—Gynecology and Obstetrics—Acute Infectious Diseases—Tests of Liver Function—Mental and Nervous Diseases—Pediatrics—Psychological Medicine—Public Health—Radioactivity and Electrotherapeutics—Renal and Urinary Diseases—Skin Diseases—Tropical Diseases—Venereal Diseases—Anesthetics—Abdominal Surgery—Genito-Urinary Surgery—Surgery of the Nervous System—Orthopedic Surgery—Rectal Surgery.

Bertwistle—Atlas of Radiographs of the Bones and Joints

By A. P. Bertwistle, M.B., Ch.B., Resident Surgical Officer, General Infirmary, Leeds. Quarto, 212 pages, 299 radiographic illustrations, $5.00 net.

Two entirely novel features characterise this volume: (1) The method adopted of combining with the ordinary radiograph a silhouette outline showing the contour of the limb, etc., in no way interferes with the bony definition, while it indicates the relation of the bones to the surface and the condition of the soft parts, a point of great value in the diagnosis of many conditions. (2) The first part of the Atlas consists of plates picturing the appearance of normal bones and epiphyses at various ages; these are arranged on left-hand pages, while the radiographs illustrating pathological conditions are arranged on the right, so that the two can readily be compared, and the corresponding numbers are indicated. The Atlas is therefore of particular value to the student or general practitioner who lacks the training and experience of the expert.

Hornibrook—The Culture of the Abdomen

The Cure of Obesity and Constipation. By F. A. Hornibrook, with a preface by Sir William Arbuthnot Lane, Bart., C.B., M.S., Consulting Surgeon to Guy's Hospital. Octavo, 80 pages, 26 illustrations, $2.25 net.

Every physician is well aware of the vast army of middle-aged or elderly men and women who are worried by excess weight and the still larger army who are troubled with constipation. Systems of exercise and of diet for reducing weight are not rare but here is one entirely practical and highly endorsed little book which any physician can confidently recommend to intelligent patients. The author describes in the clearest manner the simple, easy methods which have been proved successful by a very large number of people. Owing to the small price, this book is not sent on approval.

Meagher—A Study of Masturbation

And Its Reputed Sequelae. By John F. W. Meagher, M.D., F.A.C.P., Neurologist to St. Mary's Hospital, Brooklyn. Consulting Neurologist to the King's Park State Hospital, Ex-President of the Brooklyn Neurological Society, etc., etc. Small octavo, 70 pages, $1.50 net.

Physicians, clergymen, and teachers are often consulted by parents, or the sufferers themselves, for advice in regards to disturbances which they attribute to the widely prevalent habit of masturbation. Dr. Meagher presents in very concise form the essential features of this little understood subject so that all from whom advice is sought may be better equipped to render effectual aid. The price is a trifle. Please do not ask us to send this book on approval.

Singer—Selections from Ambroise Pare

Text from Thomas Johnston's 17th Century Translation, selected and corrected. Biography, with Explanatory and Bibliographical Notes by Dorothea Waley Singer. 12 mo., 250 pages, 2 portraits and numerous text figures, $4.00 net.

Physicians and surgeons who love their profession find delight in dipping into the past, walking and talking as it were with the fathers and pioneers of the healing arts. This little book of the writings and biography of the famous Ambroise Pare should be a welcome addition to your library.

Popular Atlas of the Male Human Body

Colored plates by George M. Dupuy, M.D. Illustrated explanatory text covering the Anatomy and Physiology of the Male Human Body by Hubert E. J. Biss, M.A., M.D., D.P.H. Size 16½ x 8 inches. $2.00 net. Atlas of Female Body to be had at the same price. Invaluable for students, nurses, teachers, and general practitioners.

Whiting—Aids to Medical Diagnosis

By Arthur Whiting, M.D., Senior Physician in the Prince of Wales General Hospital, London. Pocket size, 186 pages, 16 illustrations, $1.50 net. New third edition. One of the popular Students' Aids Series.

WILLIAM WOOD & COMPANY - 51 Fifth Avenue, New York

HIPPOCRATES is said to have urged that "all instruments ought to be well suited for the purpose in hand as regards to their size, weight or delicacy." And the old instruments to be found in museums show that the Romans made every attempt to follow the advice of this learned Greek, as did the mediaeval and later instrument makers.

Throughout the past quarter century the Kny-Scheerer Corporation has effectively contributed to the development of surgical instruments, and today its products represent the furthest advancement in design, materials, workmanship. Even balance and uniform quality make them best suited for the most precise work.

Your own distributor probably has a full line of Kny-Scheerer products. If you cannot get the article you desire, write us and we will ship it direct.

Positive Diagnosis!

$5.00 Brings it to you — A Year to Pay — Win Confidence—

Doctor—Here is an equipment that will surely aid in winning the confidence of your patients, in increasing your efficiency and in widening the scope of your practice. With this famous Spencer Microscope No. 18H and the Practical Diagnostic Microscope Outfit, you have the instrumentalities for establishing Microscope diagnosis positively, without jeopardizing your reputation by waiting for more marked findings in the physical examination. Why continue in uncertainty?

New 1924 Model Spencer High-Power Microscope

With Large Fifty-Millimeter Body Tube and Side Fine Adjustment, Affording Photo-Micrographic Work and Projection.

This latest model, world-famous, genuine Spencer Microscope, with large body tube, is an outstanding example of Microscope perfection. The great advantage that this model offers is that if the time ever comes when you wish to take a picture of a specimen slide or project a slide upon a screen, this Microscope will do it while other Microscopes with the smaller size body tube will not. The advantage of the new side fine adjustment is that it greatly simplifies focusing, as the movement of the fine adjustment buttons is in the same direction as the coarse adjustment.

You Begin Practical Work the Day You Get It

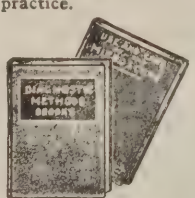
Everything is here for getting satisfactory results. The two text-books and the bacteriological chart make the work simple, the bacteriological set includes everything needed, and the instructions give the essentials of simplified microscopy.

The Free Outfit

which is included with this Microscope, is illustrated and briefly described on this page — it includes everything needed by the progressive physician to put the Microscope into immediate and profitable use. The instruction books and sheets are clear, practical and simple to follow. The accessories are complete — the very latest and best we can obtain.

Free Instructions

These valuable monthly instruction sheets, 12 in number, which we furnish free, teach you, step by step, how to use your Microscope, how to get results that will mean reputation, prestige and a better practice.

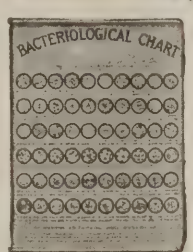


Free Manuals

Two volumes, "Diagnostic Methods" and the "Use and Care of the Microscope," by eminent authorities.

Bacteriological Chart

This large, fine bacteriological chart in colors to hang on the wall shows just how the bacteria look under the Microscope.



With this chart and this outfit you are equipped for a scientifically accurate diagnosis otherwise impossible in many cases.

Bell Jar Cover

To protect your Microscope from dust and dampness — to make it convenient to use and to greatly enhance its appearance.

Complete Bacteriological Set—Free With This Great Microscope Outfit

10 Days' Free Trial—You Take No Risk

Doctor, we leave it to you—you are the sole judge. Order this Microscope and complete outfit—try it for ten days—examine it, judge it, test it in any way you wish. Should you, for any reason, not wish to keep it, return it and we will cheerfully refund you every cent paid us. No questions—no quibbling. No ifs nor ands. Our proposition is so fair that, in justice to yourself and your patients, you cannot afford to pass it by.

Offered on Easy Rental Purchase Plan

Just $5.00 as a first payment—then you have a full year to pay the balance in such easy monthly payments that you will not miss the money. No delay — no red tape — just dignified man-to-man credit. Thousands have profited by this offer. Why not you?

Investigate — It Means Much to You

Right now — take the first step to obtain this practical, every-day help to better diagnosis. Be abreast of the times. 'Twill give you a new pride in your profession. Act — mail coupon for full information. Do it — do it today.

A. S. ALOE CO. 575 OLIVE STREET ST. LOUIS, MO.

With the Microscope we include an elaborate bacteriological set for the practical examination of blood, sputum, urine, body secretions, etc. — practically everything that is needed for efficient laboratory work by the physician—95 articles in all.

SCHELLBERG'S COLONIC THERAPY IN THE TREATMENT OF DISEASE

This book, based on twenty-five years of observation and experience with colonic irrigation, covers the subject from various aspects—scientific and practical. It embodies a discussion of the bacteriology and putrefactive processes of the alimentary canal in relation to colonic pathology as well as systemic infection. It reviews the mechanical and functional causes of constipation.

This book gives in detail the technic of bacterial implantations—Bacillus acidophilus and Bacillus bulgaricus—discusses the merits of these and the value of antiseptic irrigating solutions, and—most important of all—describes and pictures the technic and instrumentation of colonic irrigation.

Octavo, 202 pages, with 23 plates. Superfinish binding. $5.00.

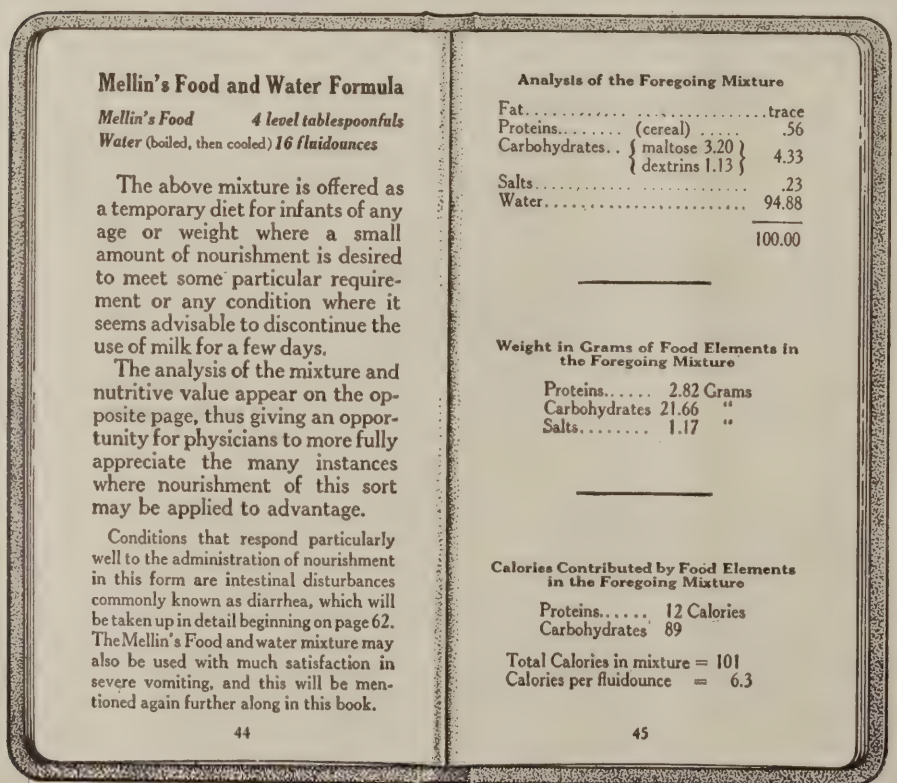
"Formulas for Infant Feeding" (20th Edition)



Mellin's Food and Water Formula

Mellin's Food — *4 level tablespoonfuls*
Water (boiled, then cooled) *16 fluidounces*

The above mixture is offered as a temporary diet for infants of any age or weight where a small amount of nourishment is desired to meet some particular requirement or any condition where it seems advisable to discontinue the use of milk for a few days.

The analysis of the mixture and nutritive value appear on the opposite page, thus giving an opportunity for physicians to more fully appreciate the many instances where nourishment of this sort may be applied to advantage.

Conditions that respond particularly well to the administration of nourishment in this form are intestinal disturbances commonly known as diarrhea, which will be taken up in detail beginning on page 62. The Mellin's Food and water mixture may also be used with much satisfaction in severe vomiting, and this will be mentioned again further along in this book.

44

Analysis of the Foregoing Mixture

Your Patient's Recreation

cannot accomplish its greatest good, if his nervous system is being subjected to the slightest irritation or depressing influence. Wearing

O'Sullivan's Heels

removes a source of irritation that, once unknown, is now recognized as an all too often factor in retarding convalescence --- the repeated jarring of the body by walking with solid leather heels on hard unyielding floors and walks.

In ordering recreation and outdoor living for weak and convalescent patients, the aid that O'Sullivan's Heels will give should not be overlooked.

O'SULLIVAN RUBBER CO., Inc., New York City

COMBINES the delightful qualities of effervescence with the well-known digestive properties of Peptenzyme.

The powerful and effective action of Peptenzyme, supplemented with the tonic and refreshing effects of effervescence, thus insures both

PERMANENT BENEFIT AND PROMPT RELIEF

in gastralgia, nervous and fermentative dyspepsia, flatulence, atonic indigestion, and to relieve the gaseous fermentation that usually causes so much discomfort in digestive disorders.

It is palatable to the nth degree and gives the physician a cooling and refreshing beverage, free from any hint of medicine, yet pregnant with therapeutic value.

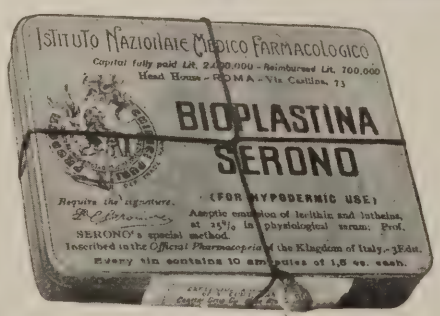
In Tissue Exhaustion



A product of the Pharmaceutical Laboratory, Istituto Nazionale Medico Farmacologico, Rome, Italy.

the essential elements must be replaced and the process metabolism stimulated.

In the emulsion of lecithin and lutheins as represented b

BIOPLASTIN SERONO

will be found a rational agent for the purpose.

The bioplastic function of BIOPLASTINA SERONO is shown by its power to increase cellular activity and to stabilize metabolism.

BIOPLASTINA SERONO is the essential substance of the cellular nucleins, and introduces into the system lecithin and lutheins, the active and phosphoric substances of embryon. Under its use follows an increase in appetite, red cells, weight and muscular strength.

As an adjunct to mercury in the treatment of syphilis, especially in the presence of cachexia, the use of BIOPLASTINA SERONO is definitely indicated. Also in anemia, rachitis, nervous exhaustion, premature senility and similar states, it will be found of more than ordinary worth.

Sample and literature sent on request.

CENTRAL DRUG COMPANY, 51 Spring Street, New York City

Sole Agents for United States, Cuba, Mexico and Canada.

WHEN THE TISSUES GET TIRED

with a general let down of vital functions, the urgent need is for a reconstructive agent both potent and easily assimilable.

MEETS SUCH A NEED.

For the purpose of building up a run down system this palatable preparation of cod liver oil is of high value.

Easily assimilated and therapeutically potent Cord. Ext. Ol. Morrhuae Comp. (Hagee) is a reliable blood-maker and tissue builder.

EACH FLUID OUNCE OF HAGEE'S CORDIAL OF THE EXTRACT OF COD LIVER OIL COMPOUND CONTAINS THE EXTRACT OBTAINABLE FROM ONE-THIRD FLUID OUNCE OF COD LIVER OIL, (THE FATTY PORTION BEING ELIMINATED), FOUR GRAINS CALCIUM GLYCEROPHOSPHATE, FOUR GRAINS SODIUM GLYCEROPHOSPHATE, ONE HALF GRAIN SALICYLIC ACID, (MADE FROM OIL WINTERGREEN), WITH GLYCERIN AND AROMATICS.

Supplied in sixteen ounce bottles only. Dispensed by all druggists.

Easily Assimilated

GUDE'S PEPTO-MANGAN

(*Liquid—Tablet Form*)

furnishes the absorbable organically combined iron

that encourages the construction of red cells.
The red cells include the Hemoglobin—
The hemoglobin supplies the Hematin—
The hematin combines with the iron—
The iron carries the oxygen—
The oxygen stimulates the waste and repair
that constitutes life and living.

It is thus of unquestioned value in **ANEMIC, CHLOROTIC** and **DEVITALIZED CONDITIONS.**

Our Bacteriological Wall Chart or our Differential Diagnosis Chart will be sent to any Physician upon request.

for

Hay Fever Prophylaxis

NOW is the time to begin the preventive treatment of the late summer or early fall cases. Ragweed Pollen Extract (P. D. & Co.) is available for diagnosis and prophylaxis; also for therapeutic treatment in cases not seen in time for prophylaxis.

The complete package contains three 5-cc vials of Pollen Extract (Nos. 1, 2 and 3), No. 2 being ten times as concentrated as No. 1, and No. 3 ten times as concentrated as No. 2. The physician is thus enabled to begin with a small dose and increase gradually, most of the diluting necessary having been done beforehand by the manufacturers. A vial of diluent is supplied for giving bulk to very small doses, such as 0.1 cc and for use in applying differential resistance tests.

Vial No. 3 can be used in diagnosis; or a special diagnostic package can be ordered containing five capillary tubes of extract—enough for five tests.

Your dealer will order for you. Shall we send you our booklet on Pollen Extracts?

PARKE, DAVIS & COMPANY
DETROIT, MICHIGAN

Pollen Extracts, P. D. & Co., are included in N. N. R. by the Council on Pharmacy and Chemistry of the A. M. A.

MERRELL-SOULE
Special
POWDERED MILK
PRODUCTS
for Infants *and* Invalids

FOUR ALTERNATIVES

1 In the diarrhoeas of dyspepsia, atrophy and cholera infantum—*a milk high in protein and low in whey salts and lactose.*

2 When breast milk is not well tolerated—*complemental and corrective feedings of a prophylactic food are preferable to discontinuance of nursing.*

3 When breast milk is insufficient—*complemental feedings of an easily tolerated milk modification.*

4 When artificial feedings must be established in the case of very young infants—*an easily tolerated milk modification.*

MERRELL-SOULE POWDERED PROTEIN MILK is a prophylactic and corrective food.

High in protein, it raises tolerances for the fat and carbohydrate, counteracts abnormal fermentations, eliminates colic, vomiting, gas and diarrhoea. It arrests losses in weight and repairs wasted tissue, because its action promotes the retention of mineral salts and fixed tissue water.

The physician will find it an ideal "alternative food" when indicated.

MERRELL-SOULE POWDERED PROTEIN MILK

Reliquefied 11 parts water and 1 part powder
(Approximating Finklestein's Formula)

Protein	3.16
Butterfat	2.25

Following the Acute Infections

prompt and uncomplicated recovery almost always calls for the systematic use of an efficient restorative tonic—a preparation that will place the least possible burden on the digestive and assimilative functions of the body, but will at the same time supply the support so urgently needed by weakened and exhausted tissues.

The constantly increasing number of medical men that have come to rely on

Gray's Glycerine Tonic Comp.

as a reconstructive tonic, tell beyond all question of its efficiency for the foregoing purposes. Under its use, functional activity is promptly increased, the nutrition is rapidly improved, and the defensive forces of the body are substantially raised.

Gray's Glycerine Tonic Comp. is thus recognized by the busy practitioner as a body-builder to which he can "pin his faith" as a dependable means of promoting convalescence and hastening recovery.

A trial of this reliable tonic will show its exceptional value following the acute infections prevalent at this season of the year.

135 Christopher St. **The Purdue Frederick Co.** New York

Valentine's Meat-Juice

For **Quieting** the **Irritable Stomach** in **Pregnancy**, for **Rapidly Restoring** the **Vital Forces** in **Hemorrhage**, for **Sustaining** and **Strengthening** in **Long** and **Exhausting Labor**, **Valentine's Meat-Juice** is extensively employed in

Obstetrical Practice.

Dr. E. Duloroy, *Physician Accoucher to the International Hospital, Paris, France:* "A young accouchée, in a very weak condition and suffering from stomach trouble, could retain no food, but was able to assimilate VALENTINE'S MEAT-JUICE given at first in small doses. An improvement was quickly visible, the patient recovered her strength and is today in good health."

Dr. Javier Ortis y Ferrer, *Physician to the Municipal Charity of Madrid, Spain:* "VALENTINE'S MEAT-JUICE has given the happiest results in cases of debility and in the asthenia produced by operations of confinements. In some cases of Tuberculosis it restored exhausted strength, and in every case where organic exhaustion manifested itself as an effect of disease."

Physicians are invited to send for brochures containing clinical reports.

For sale by American and European Chemists and Druggists.

VALENTINE'S MEAT-JUICE COMPANY,

VALENTINE'S PREPARATION
NUTRIO PERVIE
MEAT JUICE.
The result of an original Process of Preparing Meat, and extracting its Juice, by which the elements of nutrition are obtained in a state, ready for immediate absorption.
DIRECTIONS.—Dissolve one teaspoonful of the Preparation in two or three tablespoonfuls of cold or warm water. The use of boiling water changes the character of the preparation.

Miscellany.

Antiquity of Dentistry.—The great antiquity of the science of dentistry is commented on in a recent number of the California *Dental Hygienist.* Herodotus wrote about the practice among the Egyptians. The Laws of the Twelve Tables, dating from the fifth century B. C., provided that when "teeth were bound with gold," it was lawful to burn or bury the gold with the body of a dead person. In Etruria not many years ago a human skull was exhumed which had a set of animal's teeth artificially inserted in it. Galen was the first physician to mention treatment of the teeth. Dentistry as a science, however, may be said to date from 1839, when Richard Newton described the organic relation of the vascular and soft parts of the frame and the hard parts of the teeth. The first dental school established in the United States was in Baltimore. It was founded in 1839.

Medical Magic.—Isador H. Coriat (*Annals of Medical History,* September, 1922) approaches the subject of medical magic from several viewpoints. He first reviews works that have played important parts in the history of this line of thought—Blueler's book on artistic thinking and Frazer's *Golden Bough.* Primitive man as a result of his limited experience knew principally contact and similarity and by these principles sought to control the mysterious powers of nature. Certain men of the tribe, more clever and perhaps more unscrupulous than the rest, sought to gain power over their fellows and thus acquired social and political leadership. At first they were the magicians, and later the medicine men, claiming control over the life principle, the cure of disease, and the avoidance or postponement of death. "In the animistic stage of human culture, man ascribed omnipotence to himself, this is magic; in the religious stage it was ceded to the gods, this is prayer; in the scientific stage man ceased to believe in his own omnipotence or that of anthropomorphic agencies, but ascribed it to the blind forces of the universe, this is energy."

The idea of a source of magic was wholly lacking in the undeveloped and primitive mind. Magic was essentially based on charms, either according to the law of similarity, which is called homeopathic magic, or the law of contact or contagion, which is called contagious magic. "The primitive magician or medicine man had a knowledge of magic only from what he felt were its practical results . . . and he never analyzed the mental processes on which the practice was based. . . . Consequently he remained in complete ignorance of the pathological processes of disease, and of the physiological or psychological readjustments, by which disease is ameliorated or cured." In modern medicine, the administration of certain ductless glands resembles the homeopathic medical magic of primitive man. Magic is a precursor of religion. The idea of a remote deity in very primitive societies had little effect on practical life, therefore man's gods devolved on his chiefs, magicians or medicine men, who became human interpreters of divine functions.

Dr. Coriat next outlines certain "cures" based on the theories of medical magic. The Hindoos recited a spell that banished jaundice to its yellow source, the sun. In Germany yellow turnips, gold coins and rings, saffron, etc., are considered remedies for jaundice. An ancient Indian cure for alopecia was for a doctor dressed in black who had eaten black food to pour before dawn the solution of certain plants, probably dark and hairy, on the patient's scalp. If you have pimples, watch for a falling star; while you are looking at it wipe off the pimples, which will fall to the ground with the star. Other strange cures are quoted for vomiting and tumors, the use of the placenta and the umbilical cord in magic, the treatment of wounds and dropsy, and the taboos of menstruation, childbirth, abortion and miscarriage, and the couvade.

All of medical magic is unconsciously governed by what men wish instead of by the actual facts of the disease. It is a sort of undisciplined or undirected primitive thinking, in contradistinction to modern scientific medicine, which is of the nature of directed or disciplined thinking. There still exist in all of us remnants of the beliefs and tendencies in magic, one of the best examples of which is the blind and uninquiring use of medical lore accumulated in past centuries, and based upon loose methods of thinking before clear scientific conceptions had been formulated. To advance, medicine must be satisfied with nothing but facts, with disciplined thinking.

Molecules Studied by Motion Pictures.—Movies to study the motions of molecules were described by Prof. Wesley G. France, of Ohio State University, in a paper delivered before the American Chemical Society at its recent meeting in Washington. The motion pictures were those of the "Brownian movements," or irregular jerkings of very small particles immersed in fluids. The movements are caused by the jolting of fast moving molecules against the floating particles, and although the molecules themselves cannot be seen, many things about them may be learned from a study of these Brownian movements. So Professor France took motion pictures of particles of basic carbonate of lead, about 1/25,000 of an inch in diameter, a powerful microscope being attached to the camera. The negatives thus obtained were then projected on a screen so that a total magnification of from 50,000 to 200,000 diameters was obtained. Measurements of the wiggling of the particles of lead carbonate were then made under varying conditions.

Pioneers of Public Health.—(*Nation's Health.* February, 1924.) The American Public Health Association originated at a meeting of nine men in April, 1872, in the office of the New York City Board of Health. They were enthusiastic over the possibilities of an organization working for the good of the people and met again on the evening of the same day in the old New York Hotel and discussed plans. Dr. Stephen Smith acted as chairman, and a general meeting for all interested in public health was planned for September. At this meeting a constitution was adopted, committees appointed, and an organization effected. Dr. Stephen Smith, first president, was influential in creating the Metropolitan Board of Health in 1866, he drafted the bill for the National Board of Health, and the law establishing the New York State Board of Health.

In recommending an infant food —consider its nutritive value first

Cleanliness, digestibility, and palatability are also of importance, but without nutritive value any food would be useless as a body builder.

FOR the infant, breast milk furnishes all of the requirements mentioned. There is no need to seek further for a better food because no one has as yet been able to prepare a formula which can be considered anything other than a second choice.

As a breast milk substitute there is no better food for the infant than Eagle Brand Milk. For more than four years the largest child-feeding clinic in the history of the world has been maintained in the Near East, and Eagle Brand Milk has met every requirement for a complete milk food for the infants and older children throughout this period.

Reprints of clinical experiments with sweetened condensed milk will be sent upon request.

HACKENSACK, - - - - - NEW JERSEY, U. S. A.

Antiquity of Measles.—Undoubtedly measles is as old as the race, but it was first distinguished from smallpox in the tenth and eleventh centuries; we owe this differentiation to the observation of Arabian physicians. These observers recognized that having the measles did not give immunity to smallpox, and that having smallpox did not give immunity to measles. As a result of careful study of both diseases, they were able to point out the difference in the eruptions. Measles continued to be confounded with scarlet fever until the latter half of the seventeenth century, when the English of that time, Sydenham, pointed out the difference in the symptoms and in the eruptions.—Dr. V. C. Vaughan in *Hygeia.*

Changes in Corsets.—The change in fashion from the narrow waist is ascribed to Sarah Bernhardt who appeared as a boy in *L'Aiglon.* It is certain that the straight front corset appeared shortly after that time in 1900. The narrow waist persisted, however, until 1905, when it gradually gave way to the normal female figure with a Venus de Milo waist. From 1920 to 1922 it went still further until there was no waist at all and the desirable figure was the appearance of the immature girl of sixteen, theoretically cylindrical without a suggestion of roundness in contour. This boyish figure is a struggle to appear young and unspoiled. It is perhaps the least harmful of any of the corset fashions since the time of Cleopatra.—*Physical Exercise for Daily Use,* by Crampton.

The History of Pulse Timing, With Some Remarks on Sir John Floyer and His Physician's Pulse Watch.—Jacob Rosenbloom (*Annals of Medical History,* March, 1922). The pulse was probably first counted with the pocket water clock, used by Herophilus, the great physician of Alexandria. He called his instrument a clepsydra. Praxagoras of Cos, the teacher of Herophilus, was the first physician to use the pulse as an aid to diagnosis. In the works of Herophilus we find the pulse described with great detail.

Cardinal Krebs (1401-1464), the German theologian, has been declared the first man to suggest using the watch in timing the pulse, but Luciana, the Italian physiologist, claims that Cusanus in 1565 was the first to use a watch to record the rate of the pulse. William Harvey is credited with using the watch for counting the pulse rate. Galileo counted his own pulse in testing the pendulum's vibration. This led him to the idea of counting the pulse by means of a pendulum, using it somewhat as a metronome is used in keeping musical time. This apparatus was welcomed by physicians and was long used under the name of *pulsilogia.* Sanctorius (1561-1636), a professor of Padua, described a pulsilogium invented by him. Kepler in 1600 counted the pulse in timing astronomical phenomena. Théophile de Bordeu (1722-1776), founder of the Vitalistic School of Montpelier, developed a complete classification of the pulse, describing it as critical, compound critical, simple critical, noncritical, nasal, tracheal, gastric, renal, uterine, seminal, etc. The most important work of Sir John Floyer (1649-1743), one of the most original physicians of his time, was entitled The Physician's Pulse Watch. He was the first to make regular observations on the rate of the pulse, counting the number of beats in a minute by the watch. He describes the pulse of age, of youth, of pregnancy, exercise and sleep, and tells how diet, blisters and the weather affect it. The ordinary watch used in Floyer's time had a single hand, and recorded only the hours. His physician's pulse watch ran for one minute only. Floyer's method of using a watch for counting the pulse was taken up and continued by Louis, the famous French clinician, and, through the efforts and influence of the Dublin school came into common use in medical practice. Sir William Osler writes of Floyer's book: "The doctrine of the pulse reached such extraordinary development that the whole practice of the art centered around its different characters. There were scores of varieties, which in complication and detail, put to confusion the complicated system of the Graeco-Roman writers. The basic idea seems to have been that each part and organ had its own proper pulse, and, just as in a stringed instrument each chord had its own tone, so in the human body, if the pulses were in harmony, it meant health; if these were in discord, it meant disease. These Chinese views reached Europe in the seventeenth and eighteenth centuries, and there is a very elaborate description of them in Floyer's well known book. And the idea of harmony in the pulse is met with unto the eighteenth century."

Floyer's work on asthma gives the first account derived from dissection of emphysema, the observation having been made on a broken-winded mare. He distinguished it clearly from spasmodic asthma, from which he himself was a sufferer. He was interested also in the study of prophecy, and wrote the first book on the diseases of old age. He advocated cold baths, and had a cold bath built in the neighborhood of Litchfield. His book on the subject is entitled the History of Cold Bathing, Both Ancient and Modern.

The Demonstration of Urobilin in the Blood and in Body Fluids.—Oskar Weltmann and Wilfried Löwenstein (*Wiener Archiv für Medizin,* October, 1923) assert that the demonstration of urobilinogen in the serum is possible with the simplest methods much more frequently than would be expected from the reports in the literature. They found urobilinemia constant in croupous pneumonia, very frequently in severely decompensated valvular lesions with congestion of the lung and liver, relatively frequently in catarrhal icterus and almost always in cholelithiasis in the stage of urobilinuria. Under certain conditions the demonstration of urobilin in the serum has a diagnostic significance in pneumonia. Urobilinemia should not be considered prognostically unfavorable in pneumonia. In valvular lesions the demonstrability of urobilin in the blood runs parallel with the condition of severe decompensation. In diseases of the liver its clinical significance is at the present time problematical. The investigations on the urobilin contents of blisters showed positive results only when the urobilin was also demonstrable in the blood. A definite interpretation of the demonstrability of urobilin in the serum is not possible at the present time. It appears as if the relationship of the structure of albumin of the blood serum was the determining factor in the necessary conditions for the entrance of the urobilin into the blood.

Lupulin-Agar in Intestinal Neurosis

In painful digestion and chronic gastro-intestinal affections Lupulin is a desirable antispasmodic, and its prolonged administration does not produce a habit. When combined with Agar as a vehicle a remedy is obtained that slowly liberates the Lupulin through osmosis, allowing the sedative to cover a large area before being absorbed. Agar is eliminated from the intestinal tract undigested, absorbs a considerable quantity of fluid and increases the bulk of the stool. This property is useful in conditions where the feces are dry and reduced in quantity.

A trial package will be sent postpaid for 60 cents.

EIMER & AMEND
ESTABLISHED 1851
Third Avenue, 18th to 19th Street New York

Reduction in the Use of Narcotics.—In a recent report, the director of the Narcotic Division of the Prohibition Unit, Department of Health of the City of New York, says that the importation, sale and use of narcotic drugs in the United States is decreasing. The importation of opium has decreased from 471,000 pounds annually for the ten year period prior to the effective date of the Harrison Narcotic law in 1915 to slightly less than 136,000 pounds in 1922, decreasing the per capita consumption thirty-six grains annually to approximately seven grains, or in morphine, the equivalent of seven eighths of one grain. For the six months ending December 31, 1923, the importation of opium particularly showed a decrease, while the sales of the various alkaloid derivatives of opium fell off fifty per cent. over the previous six months. Importation of coca leaves decreased from 626,341 pounds in 1920, to 342,260 pounds in 1923, a drop of approximately fifty per cent. in three years. The report adds: "The decrease in the importation, sale and use of narcotic drugs may be accounted for in part by the fact that non-habitforming synthetic compounds and preparations now on the market are replacing the habitforming narcotic drugs; to a more rigid enforcement of the narcotic laws and to the lack of new recruits to the great body of addicts."

Summary of Provisional Birth and Mortality Figures for 1923.—The Department of Commerce announces that birth rates for 1923 were lower than for 1922 in twenty-one of the twenty-seven states for which figures for the two years are shown in the following summary: The highest 1923 birth rate (34.8 in 1,000 population) is shown for cities of Wyoming and the lowest (15.6) is for rural districts of Montana. Death rates for 1923 were slightly higher than for 1922 in twenty-five of the thirty-six states shown for both years. Three states, Connecticut, New York, and North Carolina, have the same rates for 1923 as for 1922 and eight states, Colorado, Idaho, Montana, Nebraska, Oregon, South Carolina, Utah, and Washington, have lower rates in 1923. The highest 1923 death rate (20.3 in 1,000 population) is shown for cities of Mississippi and the lowest (6.5) for the rural districts of Idaho. Infant mortality rates for 1923 are generally higher than those for 1922, as seventeen of the twenty-seven states show higher rates in 1923. The highest 1923 infant mortality rate (117) appears for cities of South Carolina and the lowest (51) for the rural districts of Utah and the cities of Washington.

Scientists Detect Art Frauds.—Art collectors can now add another weapon to their armory against the unscrupulous art faker and seller of false or retouched old masters. Two French scientists have invented a method by which retouching may be detected through the use of different sorts of light thrown on the suspected painting. The use of these various colors throws the retouchings, scrapings, and false signatures into prominent relief. If the picture be illuminated by ultraviolet light some pigments, such as zinc white, become fluoroscent. A false Renoir was detected by a spectrographic analysis of a small quantity of pigment scraped from the picture. This was found to be cadmium yellow, while Renoir always used chrome yellow.

Patients suffering from

CHRONIC RHEUMATISM

frequently constitute a vexing problem. They drift from office to office, from doctor to dentist, from physiotherapeutic institutions to hot springs, and return without permanent relief.

Certain strains of streptococci have been identified as the etiologic factor by many authorities. Doctor Robes' Anti-rheumatic Injections contain bichloride of mercury and guaiacum which have a specific action and search out all systemic foci of infection.

In your next case of acute or chronic rheumatism make your own clinical studies of the efficiency and safety of the treatment, which may be commenced before or after removal of all known foci of infection.

For clinical reports and information write to
Dept. 21, 110 West 40th St.,
New York, N. Y.

ROBES' INTRAVENOUS PRODUCTS, Inc.

"It Takes More Than One Man To Make An Army"

It requires a carefully selected combination of synergistic agents to overcome uterine or ovarian irritation, inflammation, dysfunction or atonicity.

HAYDEN'S VIBURNUM COMPOUND

has for many years met such requirements and has won the right to be regarded as the remedy, par excellence, in the treatment of

DYSMENORRHEA, MENORRHAGIA, CONGESTION, CRAMPS, NEUROSES OR PUBERTY, PREGNANCY OR CLIMACTERIC, ATONY, SUBINVOLUTION, LEUCORRHEA.

One or two teaspoonsful in twice the volume of hot water sweetened with sugar t.i.d.

Send for sample and literature

NEW YORK PHARMACEUTICAL CO.
Bedford Springs, Bedford, Mass.

CHRONIC CONSTIPATION

is most successfully treated by

a lubricating agent that will not upset the stomach, that effectually lubricates without impairing nutrition and will not cause seepage. The best agent to secure these results is the EMULSIFIED OIL in

ANGIER'S EMULSION

Its use eradicates the drug habit and the constant recourse to laxatives and aperients and furthermore ANGIER'S promotes nutrition.

Sig.: 1 or 2 tablespoonfuls in glass of hot water twice daily.

Free trial bottles for the asking

CHLORO-CALCIUM

Elixir Calcium Chloride S & D.

Each fluidrachm of Chloro-Calcium contains five grains of pure Calcium Chloride.

The current medical literature contains many articles and references on the therapeutic value of Calcium Chloride, as a hemostatic agent and in the treatment of some forms of skin diseases and in the prevention and treatment of hay fever.

Unfortunately Calcium Chloride, as ordinarily prescribed, is obnoxious to the average patient. In our Elixir of Calcium Chloride we have succeeded in so disguising its unpleasant character that it is perfectly acceptable to the most fastidious patient.

Sample supplied upon request.

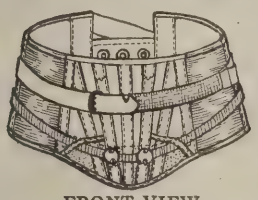
TOSIS BANDAGES

DR. AARON'S

For Gastroptosis, Enteroptosis, Drooping Abdomen, Visceral Weaknesses and General Abdominal Support



FRONT VIEW

This bandage was designed by Dr. Charles D. Aaron of Detroit, and is described in detail in Dr. Aaron's treatise on diseases of the digestion organs. We have made upwards of 3,000 of these bandages which provide a wonderful support and uplift for displaced viscera and prolapsed organs.

The cuts show its special design—straight well-stayed front, elastic sides, post and eyelet back, and an uplifting truss band behind which in front is a specially designed tosis pad. This truss band is light, flexible and uplifting to the exact degree desired. Our method of manufacture insures a perfect fitting support.

Made to order only. Net price $12.25. Give body measurements at pubis, crests of ilium and six inches above pubis, also width of pelvis between anterior superior iliac spines. Fitted at office or sent postpaid by mail.

The Door to Our Laboratory Is Never Locked

When the doctor encounters a patient who is taking the SERVICE of the National Bureau of Analysis we wish him to realize that the periodical urinalysis is in the hands of competent people.

We invite a visit and inspection from any medical man to our laboratory. Here he will find the analysis being made by an experienced and fully qualified staff under the direction of a physician.

The samples are checked and tabbed by a system which prevents the possibility of either mistake or carelessness.

When the analysis discloses a serious condition, we immediately advise the subscriber to consult his physician.

We do not make a physical examination as this is the province of the subscriber's own medical man.

WASSERMANNS

Many refinements of the classical Wassermann Test, as performed in our laboratories, enable us to frequently pick up positive or doubtful cases which, by the usual methods, would escape detection. We employ the Icebox Fixation exclusively with plain alcoholic extract antigen, THUS OBTAINING THE MAXIMUM NUMBER OF POSITIVE FINDINGS WITHOUT THE DANGER OF FALSELY POSITIVE REACTIONS.

The Wassermann and other complement fixation tests are performed in duplicate sets daily. Price $5.00.

Price list covering all laboratory tests and containers with directions for taking specimens, sent gratis.

The Grain Food Supreme
—at its best

Food authorities rate oats as the most valuable of grain foods. No other cereal ranks so high in calories, protein, calcium.

Enjoyment of this great grain dish depends on quality, the quality of Quaker. Flaked from the finest oats grown — plump, full-flavored. Only 10 pounds to a bushel good enough. That's why Quaker Oats is everyone's favorite breakfast.

A Physician's Apartment

THE location of this four-room suite, on the Park Avenue front of 760 Park Avenue, will be recognized as unusually desirable for a physician whose practice is among the better New York families.

Consisting of a Waiting Room, Secretary's Office, Consulting Office and Treatment Room, it was especially planned for the comfort, convenience and needs of the busy physician. The rooms communicate and can also be reached independently through a private corridor.

760 Park Avenue is a 100 percent cooperatively-owned apartment of distinctive character, designed and erected by a syndicate whose reputation for fine workmanship is widely recognized.

You are invited to inspect this splendid office and the plan under which it is for sale.

Mead's Infant Diet Materials are advertised only to physicians. No feeding directions accompany trade packages. Information in regard to feeding is supplied to the mother by written instructions from her doctor, who changes the feedings from time to time to meet the nutritional requirements of the growing infant. Literature furnished only to physicians.

Mead Johnson & Company, Evansville, Indiana

SUPERLATIVES ARE UNNECESSARY—
WILD STATEMENTS UNCALLED FOR.

Pediatricians, Physicians and Nurses know that when speaking or writing about a product such as DRYCO whose very name has a high valuable significance to them, there is no necessity for the use of superlatives, nor to make wild statements.

They know that next to mother's milk, "DRYCO" is the BEST FOOD in its physiological aspect.

DRYCO supplies the food solids from pure fresh cow's milk.

ITS protein content, or muscle building element, is easily digested.

ITS butter fat is in a condition so that it is readily absorbed.

IT is free from all harmful bacteria, and

ITS vitamin content is preserved.

DRYCO has solved the perplexing problems of bacteriological contamination and fermentative changes, which render cow's milk so difficult to handle.

Please take note that we shall be glad to send you Samples, Directions, Feeding Tables, and our very interesting little booklet, "The Doctor's Rubaiyat", on request.

THE DRY MILK COMPANY, 17 Park Row, New York, N. Y.
